Erklärung

Ich versichere hiermit, dass ich meine Bachelor Thesis mit dem Thema: *Implementation and Evaluation of an Incentivized Blockchain-Based Deposit-Refund System for Bottled Beverages in Germany* selbstständig verfasst und keine anderen als die angegebenen Quellen und Hilfsmittel benutzt habe. Ich versichere zudem, dass die eingereichte elektronische Fassung mit der gedruckten Fassung übereinstimmt.

Stuttgart, 3. September 2018

Niklas Sauer

Preface

This thesis presumes background knowledge in the realm of blockchain technology. At the very least, the concepts presented by Bitcoin should be familiar to the reader in order to ensure full comprehensibility of the technical proceedings presented and comparisons drawn herein. Published by the National Institute of Standards and Technology, [\[75\]](#) may be consulted as a general introduction to this landscape. The author's knowledgeability has been demonstrated through the research conducted in [\[58\]](#).

Abstract

Germany's deposit-refund system has missed its opportunity to halt the influx of one-way packaged beverages. Shockingly, the system even benefits bottlers as they are allowed to pocket all non-claimed deposits. New measures will be needed to increase the portion of reusable bottles and thus support the environment through the smaller ecological footprint offered.

This thesis introduces the concept of an incentivized deposit-refund system, in which consumers are rewarded for choosing reusable beverage packaging but also penalized for throwing away one-way bottles. Several of its core features speak for a blockchain-based approach. To this end, the research question is as follows: *What would such an implementation look like, and are there any special considerations to be made?*

This question is answered by carrying out the end-to-end development process which includes design, implementation and testing. Moreover, the study aims to highlight the major obstacles companies must expect when developing applications for decentralized platforms. Although the results indicate that its capabilities are sufficient, the platform does not currently scale enough to support this particular workload.

1. Introduction

1.1. Motivation

Plastic or aluminum packaging represents a lightweight and durable alternative when compared to glass. The impact of lightweight materials on shipping costs is non-negligible and has, therefore, been leveraged in the beverage industry for the past 30 years. Simultaneously, the portion of reusable bottles (Mehrwegflasche) has steadily fallen (from 72% in 1991 [29, p. 1] to 43% in 2015 [30, p. 4]), which prompted German lawmakers to introduce a system of returnable one-way bottles (Einwegflasche) in 2003 on which a deposit is paid [61, p. 53].

Contrary to expectations [44, p. 10], this regulation has not stopped the influx of one-way bottles but has, rather, benefitted bottlers. Whenever consumers pollute by leaving behind one-way bottles, an instant 25 cent profit — assuming that no one else has returned them — is generated for the producer. This passive profit was estimated to have reached up to 192M€ in 2011 alone [54, p. 245].

Ideally, this pollution of the environment should be penalized by splitting the resulting non-claimed deposits of one-way bottles between environmental agencies and those consumers who regularly purchase reusable bottles, an act which saves more resources. As a further consequence, those consumers who repeatedly neglect to return their one-ways should be required to pay a higher deposit. Such a revised approach can hopefully maximize the number of returned one-way bottles and effectively steer users towards reusable ones. Otherwise, a further decline may be inevitable, which has been shown to have had a direct negative impact on global warming, in addition to the excess amount of waste produced thus far [39].

When considered on a case-by-case basis, this problem inherently deals with deposits of very low extrinsic value. Moreover, such a system has to manage account balances and track the movement of value, increasing the appeal and likelihood for external attacks. Therefore, implementing the proposed approach by utilizing smart-contracts and micro-transactions on the blockchain may be considered when choosing the underlying infrastructure. Yet what would such an implementation look like, and are there any special considerations to be made?

1.2. Goals and Scope

Since no research on the feasibility of this approach has been undertaken for an application as specific as this one, the study focuses on the end-to-end development process, including design, implementation and deployment. The objective of the research is to guide Hewlett Packard Enterprise ([HPE](#)) and interested parties alike in developing a mindset suitable for migrating applications onto decentralized platforms and evaluate if this blockchain-based implementation can withstand the requirements of an incentivized deposit-refund system. The results are relevant as they reduce the go-to-market time of the previously outlined solution to stop the influx of one-way bottles, which, in turn, reduces pollution and warming of the earth, a serious concern to today's society. Moreover, [HPE](#) can offer more profound blockchain-related consulting services through the insights gained.

It shall be explicitly noted that the study does not cover analyzing the effectiveness of employing such a system (i.e. reducing the share of one-way bottles) or verifying whether this represents the best possible approach. Similarly, the legal framework and ethical questions pertaining to its usage are disregarded.

1.3. Thesis Overview

?? reviews the relevant literature and is intended to answer all descriptive research questions that help define the project variables. The key concepts are then applied in ?? as part of the architectural overview derived from the (non-)functional requirements of an incentivized deposit-refund system given earlier in the chapter. At the same time, these requirements will also act as the criteria used to evaluate the forthcoming implementation. ?? then describes the procedure to implement the solution, followed by ??, in which the test-driven development approach will be presented. ?? uses the results and observations to draw a conclusion and discuss probable alternatives, as well as any limitations encountered during the study. Finally, ?? summarizes the thesis's goals, methodology and results.

2. Theoretical Framework

2.1. Deposit-Refund System for Bottled Beverages in Germany

2.1.1. Legal Basis

Anticipating the depletion of capacity at disposal sites and due to the considerable share in waste generated by packaging ¹ [44, p. 2], the German federal government enacted an ordinance regarding the avoidance of packaging waste (*Verordnung über die Vermeidung von Verpackungsabfällen*, short: *Verpackungsverordnung* - *VerpackV*) in 1991, which stipulates that packaging [68, § 1]:

- must be minimized to an extent necessary for protection and marketing of goods
- must be reused where possible
- must be recycled if reuse is not applicable

These objectives were supported by introducing the:

Obligation to take back packaging

Producers and distributors of packaging are obliged to take back packaging free of charge, restricted to those goods of type, shape, size and material found within their stock [68, §§ 4-6]. Distributors with a retail area of less than 200m² are further exempted to the same brands. This duty may only be avoided if a distributor participates in a system which ensures the periodical collection of waste [68, § 6], known and implemented as a refuse recycling system (*duales System*) in 1990 [44, p. 3].

Obligation to levy deposits on beverage packaging ²

A deposit is to be charged by the distributor that will be refunded to the purchaser upon return of the bottle. This duty is applicable on all levels of trade involving domestic beverages sold in non-reusable packaging (*one-way packaging*) [68, § 7] and

¹ Recycling rate of packaging was below 50% in the early 1990s (20% for aluminum and plastic) [44, p. 2].

² Information regarding the presumed effects and critique thereof can be found in [70, p. 630] and [69].

becomes effective as soon as the portion of reusable beverage packaging falls below 72% ³ [68, § 9].

Figure 2.1.: Percentage of reusable beverage packaging between 1991 and 2013 [29]

In 1997, the threshold to levy deposits was surpassed (comp. Figure 2.1), requiring an additional assessment of the situation to ensure that the fluctuation did not represent a short-term development [68, § 9] [44, p. 5]. Although obvious at a glance, the compulsory deposit-refund system only became official on July 2nd, 2002 [61, p. 49], after a lawsuit lead by multiple bottlers and distributors had delayed the initial announcement [36]. Introduction of this mandatory system was then scheduled for January 1st, 2003 [61, p. 53].

2.1.2. Amendments

The German packaging ordinance underwent several revisions, including a change of title to highlight the importance of recycling [67]. In the following, the most important changes affecting the current state (see Figure 2.2 on page 6) are highlighted.

1998

This amendment decreases the deposit obligation to only those beverages for which the portion of reusable packaging has fallen when compared to 1991, though still necessitates that the overall portion undercuts the threshold of 72% [40, pp. 142]. Even though all five segments have failed this comparison from 2000 onwards (comp. Table 2.1), wines, juices and non-carbonated soft drinks are exempted because

³ This percentage was derived from the weighted average of percentages of reusable packaging encountered across individual segments in 1990 [68, § 9] [57, p. 134].

their decline and market volume has not been regarded as being significant enough to justify the costs introduced with such a system [44, pp. 6, 9].

Segment	1991	1995	1998	2001	2004	2007	2013
mineral water	91.3	89.0	87.4	74.0	67.6	47.0	40.6
fruit juice & soft drinks	34.6	38.2	35.7	33.2	20.6	13.0	9.6
carbonated soft drinks	73.7	75.3	77.0	60.2	62.2	41.9	30.9
beer	82.2	79.1	76.1	70.8	87.8	85.2	85.9
wine	28.6	30.4	26.2	25.4	20.0	9.1	6.8

Table 2.1.: Percentage of reusable beverage packaging per segment between 1991 and 2013 [29]

2005

The amendment eliminates different deposit classifications down to single deposit worth 0.25 €, valid for all applicable beverages with a filling volume between 0.1 - 3.0 liters. Furthermore, [ecologically advantageous packaging](#) is permitted the same treatment and classification as that of reusable packaging which represents an important shift of thought since the sole utilization of packaging has been considered inferior to its reuse with regard to all ecological aspects [44, p. 7]. Accordingly, the new goal is to promote the use of ecologically advantageous packaging with a target of 80% market dominance [42, § 1]. This amendment also adds non-carbonated soft drinks and mixed alcoholic drinks to the list of beverages subject to deposits (irrespective of the portion of reusable packaging sold) while simultaneously protecting dietary products from deposits [38, p. 1408] [41, p. 171]. Finally, retailers are required to take back any bottles made from a beverage packaging material (glass, metal, paper and plastic) also sold by that store (brand equality for retail areas of less than 200m² still applies) [44, p. 11]. Previously, return had been limited to bottles of the same shape, size [...] and type (comp. 2.1.1). This change attempts to stop isolated deposit-refund systems which arose because discounters created their own specially shaped bottles [41, p. 168]. To conform with this change, industry and commerce established the Deutsche Pfandsystem GmbH, responsible for setting up a nationwide deposit-refund system [44, p. 8].

2008

The amendment orders distributors to clearly mark bottles as being subject to a deposit. Further, distributors are compelled to participate in a nationwide deposit-refund system in order to enable the mutual settlement of claimed deposits [42, § 9]. Lastly, the exemption for dietary products is condensed to infant nutrition. This acts as a measure to counteract increasingly false product declarations attempting to forego deposits [42, pp. 531] [41, p. 171].

After several years of negotiations, the day, January 1st, 2019 will mark the end of the German packaging ordinance since a new packaging law was passed in late 2017 [35, p. 4]. It will largely build upon the regulations previously set but will attempt to broaden its influence by including wholesale and mail-order packaging [35, p. 6]. In respect to beverage packaging, consumers must prepare to pay a deposit on carbonated juice and vegetable-nectars in addition to whey-based drinks. Also, the targeted percentage of reusable beverage packaging has been lowered to 70%. The most noticeable change will stem from a new requirement that mandates retailers to label their retail area according to the packaging type sold there [35, p. 9]. Until these changes take effect, Figure 2.2 may be used to decide whether or not a one-way packaged bottle is subject to deposits.

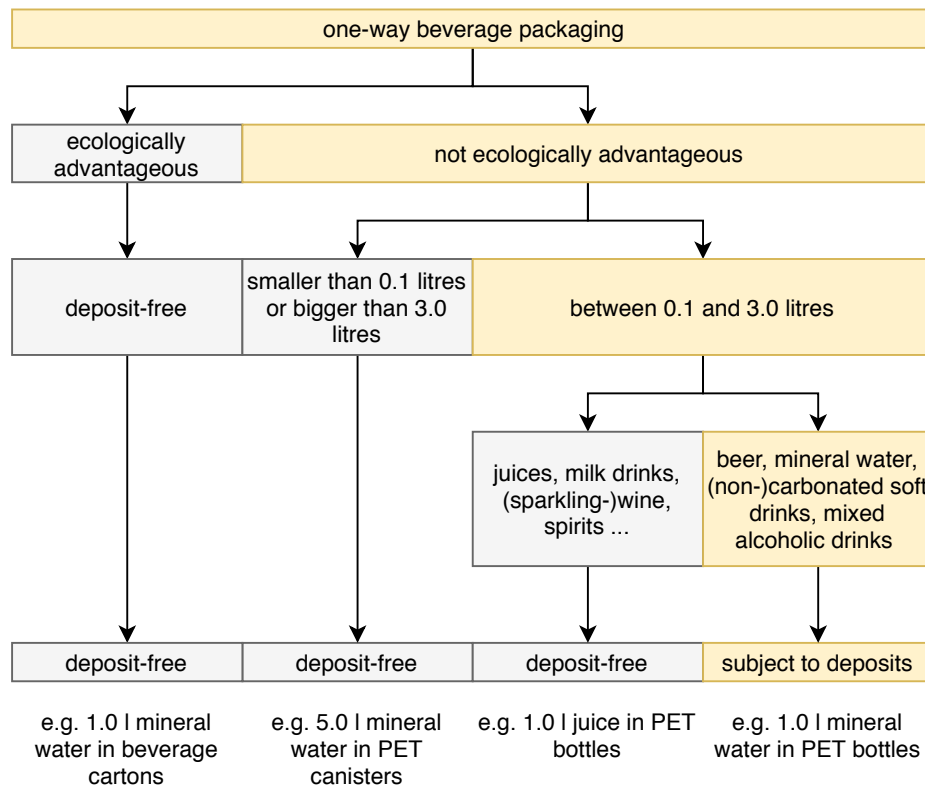

Figure 2.2.: Criteria subject to deposits (valid until January 1st, 2019) [44, p. 9]

2.1.3. Operation

Administration by Deutsche Pfandsystem GmbH

The German packaging ordinance simply assumes that a nationwide deposit-refund system will be installed by May 1st, 2006 without further specifying its exact implementation details [38, Art. 2] [42, § 9]. Therefore, Deutsche Pfandsystem GmbH (DPG) was founded in 2005 to ensure the definition of a standards framework, which includes IT-processes,

APIs and a universal security mark (see Figure A.1 on page 72) that identifies one-way packaged bottles on which a deposit is paid (*one-way bottle*). Other tasks concern the management of contracts, certifications and maintenance of a centralized database which stores information about products, participants and reverse vending machines [44, pp. 13]. However, DPG does not have access to purchasing data (e.g. number of sold and returned bottles or total amount of reimbursed deposits). This data is only exchanged between participants in the deposit-refund cycle. Consequently, DPG is not involved in the process of settling refund claims between take-back points and does not act as a central clearing house. It is exclusively responsible for providing a contractual and administrative basis needed to enable such a system [44, p. 14].

Roles

As previously indicated, participants in the deposit-refund cycle must register with DPG, accept the contractual basis for the role to be exercised and pay a yearly membership fee in order to participate. The most important roles are [44, pp. 15–16]:

Initial distributor

Puts one-way bottle into circulation. Inherently tied to role of deposit escrow account manager. Must pay a one-time fee to register a beverage (i.e. an EAN) with DPG's central database. This fee depends on the number of pieces produced of that beverage within a year.

Deposit escrow account manager

Administrates and disburses money received from levying deposit on a one-way bottle. Task may be delegated to a service provider.

Take-back point

Refunds consumer in exchange for returning bottles subject to deposit. Inherently tied to role of refund claimant.

Refund claimant

Puts in a claim to be reimbursed for making advance refunds. Task may be delegated to a service provider.

Counting center operator

Takes over role of reverse vending machine by confirming number of genuinely accepted bottles with a receipt.

Deposit-Refund Cycle

Each buyer of a one-way bottle must directly pay the designated deposit to the seller. This process starts with the initial distributor (step 1 of Figure 2.3) and is repeated for each sub-distributor until the bottles reaches a retailer which acts as the final distributor to end consumers (step 2 of Figure 2.3). After consumption, the consumer may return the packaging at any retail store obliged to take back the packaging in question (*take-back point*) (step 3 of Figure 2.3). Return may be performed manually (step 1a of Figure 2.4) or can be automated through reverse vending machines (step 1b of Figure 2.4). The former requires personnel to count the number of returned bottles and refund the consumer accordingly. Following count, the collected bottles must be shipped to a counting center which is responsible for digitally capturing each bottle (step 2a of Figure 2.4). Lastly, the bottles will be compressed to eliminate the possibility of repeated refunds. In the case of reverse vending machines, the process of counting, capturing and compressing bottles can take place locally at a retail store (step 2b of Figure 2.4). Alternatively, retailers are permitted to return the packaging to the previous distributor, thereby unwinding the deposit-refund chain. However, this practice is rarely exercised since the packaging will not be reused and transportation would only induce additional ecological and financial strain. Instead, the compressed packaging can be sold directly to recycling companies (step 3 of Figure 2.4) [44, p. 16-17].

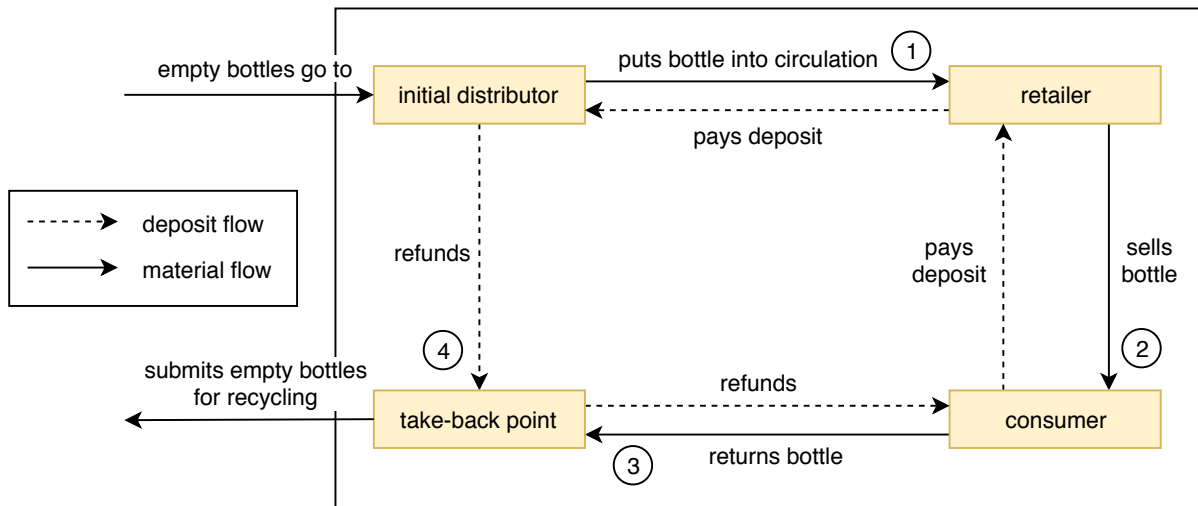

Figure 2.3.: Deposit-refund cycle [44, p. 14]

Since take-back points refund consumers independent of a bottle's purchasing location, a settlement process (*clearing*) is required to reimburse retailers for making advance refunds (step 4 of Figure 2.3). This clearing process occurs by issuing a refund invoice to the initial distributor who could then use the deposits that were originally collected by him to pay the bill (step 4 of Figure 2.4). Ideally, all accounts are balanced, meaning that all

packaging has been returned. Otherwise, an initial distributor will encounter a surplus [44, p. 17].

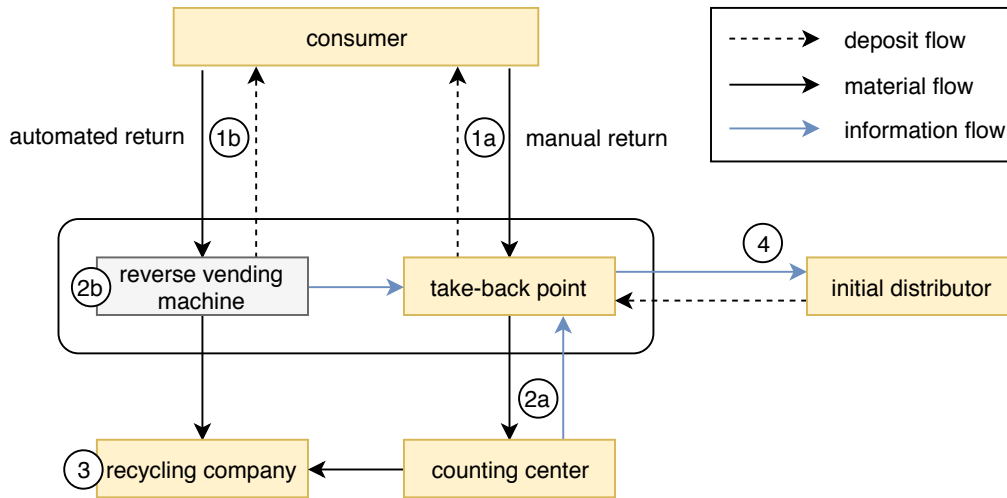

Figure 2.4.: Clearing process for manual and automated bottle returns [44, p. 18]

Refund invoices must also include data representing the number of bottles for which a refund was paid. This data originates from the return process in which each bottle will eventually be captured. Capture refers to both validating the universal security mark printed on a bottle's label (see Figure A.1 on page 72) as well as extracting the European Article Number (EAN) by scanning its barcode. By outfitting reverse vending machines with a network connection, looking up the EAN in question becomes possible, thus ensuring that a deposit for the bottle had been collected beforehand. For each valid bottle, a signed record is then produced and stored on the machine. This data must be retrieved and transmitted within one week. Likewise, retailers will receive a similar dataset when relying on a counting center. Finally, before transmitting the data, it will be anonymized by removing the return location and summing up the refunds for each EAN captured. Initial distributors must pay the invoice within ten business days or fifteen calendar days, at the latest [44, p. 18-19].

An extended diagrammatical overview of this cycle can be found in Appendix A on page 73. It includes the various scenarios encountered nowadays which lead to differently balanced accounting states. Also, the process of buying a one-way bottle from the perspective of a wholesaler or any other special entity, such as a caterer, is reflected in both figures, since these parties are ultimately responsible for returning the one-way bottles as long as the parties do not sell them to other parties.

2.2. Decentralized Applications

2.2.1. History & Raison d’Être

Johnston’s Law states that everything that can be decentralized, will be decentralized [1]. Fittingly, a new model for building massively scalable, successful and profitable applications, known as *Decentralized Applications (dApps)*, is emerging [56, p. 5] [45, pp. 1–2], suggesting that this will also become the fate of the vast majority of web software applications, since those follow a centralized server-client model in which individuals directly depend on a central power to send and receive information [56, pp. 7–8].

The architectural structure embodied by the web has not always been as pronounced as it is these days. In its early days, people would host personal servers for others to connect to and everyone owned their data. But soon, it was recognized that one individual or group could pay for the maintenance of a server and profit from users that utilize it (e.g. Amazon Web Services ⁴). Since this was easier to the average user, both conceptually and programmatically, the transition to few centralized controlling entities began [56, pp. 14].

Now, users willingly give their data to service providers in return for free usage, trusting them to not misuse or sell the data elsewhere [56, p. 24]. However, Snowden proved that this trust can, has and will be broken as long as we entrust (encrypted) data to central entities which represent a surveillance state’s dream [26] [56, p. 25]. In addition, centralized infrastructure and services increase the chances for downtime, censorship and [counterparty risk](#) [24, p. 23]. Drawbacks like these have attributed to the development of [dApps](#), first fully realized by Bitcoin ⁵ as a currency [45, p. 1] [51, p. 1]. Simultaneously, recent apps (e.g. Uber and AirBnb) attempt to decentralize real world parts of a business by providing a central and trusted data store. This foreshadows the development of decentralized applications beyond pure finances ⁶ [56, p. 15].

The concept of [dApps](#) is meant to take the web to its next ⁷ natural evolution [24, pp. 34]. Web3 represents the vision of a serverless ⁸ internet, encouraging applications to incorporate decentralized protocols in order to put users in control of their own data, identity and destiny [3]. As global economy evolves, data will become the primary form of value [56,

⁴ Amazon controls roughly 40% of the cloud market and serves customers such as AirBnb, Expedia, Netflix, Slack and Spotify [28]. Please install [2] to experience the impact of an Amazon Web Services downtime.

⁵ BitTorrent, as an earlier example, depends on centralized trackers for data discovery [56, p. 26].

⁶ Supports the blockchain evolution theorem proposed in [63].

⁷ Web 2.0 describes the evolution towards user-generated content, responsive interfaces and interactivity [24, p. 34].

⁸ Not to be confused with the centralized Function-as-a-Service offerings detailed in [59].

p. 25], leading Raval to believe that “[dApps] will someday become more widely used than the world’s most popular web apps” [56, p. 5].

2.2.2. Definition

Developers have different opinions on what exactly a dApp is or which components constitute it. Some think that no central point of failure is all it takes, whereas others name more specific requirements [56, p. 9]. The following section will chronologically examine the various definitions available in order to derive one which will be used for the remainder of this thesis.

2014

Buterin introduces the concept of a dApp as part of Ethereum’s white paper. A complete dApp should consist of:

- low-level business-logic components
- high-level graphical user interface components

He goes on to state that “the blockchain and other decentralized protocols will serve as a complete replacement for the server for the purpose of handling user-initiated requests. ... Decentralized protocols ... may be used to store the web pages themselves” [32, p. 34].

This vague explanation is expanded through a consequent blog post (2014) in which Buterin formally defines the concept as being a superset of *smart-contracts* [31]:

Smart-contract

Mechanism involving digital assets and a fixed number of parties, where some or all of the parties put assets in and assets are automatically redistributed among those parties according to a formula based on certain data that is not known at the time the contract is initiated.

Decentralized application

Similar to a smart-contract but with unbounded number of participants and not necessarily of financial nature.

2015

To be considered a [dApp](#), Johnston et al. assume that an application [45, p. 2]:

- is **open-source**, operates autonomously and adapts its protocol with user consent
- stores its data and records of operation in a **public blockchain**
- uses a **token** necessary for accessing it and rewarding contribution of value
- generates its tokens according to a predefined **cryptographic algorithm**

Moreover, he classifies [dApps](#) based on whether they have their own blockchain (Type I), use that of another [dApp](#) (Type II) or use a type II [dApp](#) as its underlying protocol (Type III). The latter is also known as a protocol [45, pp. 3–4].

2016

Although similar to the elements proposed priorly, the definition given in *Decentralized Applications: Harnessing Bitcoin's Blockchain Technology* highlights their importance and by such requires that a profitable [dApp](#) [56, pp. 9–14]:

- is **open-source** to achieve transparency and gain trust among users
- achieves **decentralized consensus** on application-level constructs (e.g. high-score)
- uses an **internal currency** for access, reward and monetization
- has **no central point of failure** so that it cannot be shut down

2018

Finally, Antonopoulos and Wood (co-founder of Ethereum) back up and clarify Buterin's design guidelines by stating that a [dApp](#) is composed of at least [24, p. 34]:

- **smart-contracts** on a **blockchain**
- a web frontend **user interface**

Optionally, a [dApp](#) may rely on other decentralized components such as:

- decentralized storage
- decentralized messaging

Derived Definition

An application is considered to be a Decentralized Application (**dApp**) if it exhibits all of the characteristic features marked as a *must*. Secondary or recommended traits are labelled as *can* or *should* respectively.

It must be noted that this definition will not differentiate between type II and type III **dApps** because the former can be regarded as a dependency of the latter.

Open-source

Traditional business models require a company's service to be better than that of its competitors. By open-sourcing a solution (both frontend and backend), copying becomes inevitable [56, p. 10]. However, users will want to remain with the team that is best suited to maintain the application [56, p. 11]. Therefore, developers should not fear trading secrecy for transparency. Transparency removes a barrier to adoption as users are no longer required to trust that an application works as advertised [56, p. 9]. Additionally, open-source development often sparks the attraction of enthusiastic developers who contribute freely [56, p. 11]. A decentralized application:

- *must* be deployed visibly (i.e. the executed code can be inspected by a user)
- *should* be developed on an open-source platform

Johnston et al. call for an application to only alter its protocol by the consensus of its users. Yet, it can be argued that this does not represent a core property of a **dApp** since users can revert to the desired state at any time by forking the project.

- *can* require the consensus of users to upgrade its protocol

Decentralized consensus

Usually, application-level constructs (e.g. usernames, high-scores or status updates) are managed and modified only through the centralized application provider, thereby ensuring a single and consistent state (*singleton*). Luckily, blockchains provide the means to reach consensus in a decentralized manner. Traditionally, this is only applied to transactional logs [51, p. 1]. Extending this consensus mechanism to cover the outcome of a computer program, and consequently storing the result on a blockchain for future retrieval as an input would enable virtually any application. Seeing that such an application would always have a single globally valid state, the underlying infrastructure can be colloquially termed a world-computer.

Raval, Antonopoulos and Wood refer to these programs as smart-contracts and equally expect them to be secured by and executed on a blockchain [56, p. 13] [24,

pp. 23, 34]. It must be noted that Buterin consistently denotes smart-contracts as being a subset of contracts. The former is of financial nature and may involve redistributing digital assets among parties or unlocking value depending on the conditions met [32, pp. 1, 13]. The latter can be used to encode arbitrary state transition functions required to build decentralized applications which may also issue tokens [32, pp. 1, 19]. For simplification purposes, the business logic of both applications types will be referred to as smart-contracts.

- Type I *must* achieve decentralized consensus on state-transitions
- Type II *can* only modify its data via a smart-contract

Finally, in order to achieve decentralized consensus, it is ultimately necessary to have a complete picture of the state-transitions (*transactions*) which have been applied by a network. While theoretically possible, applications have never been known for only storing their transactions, due to the long processing time needed to rebuild the most current state (*data*).

- *must* store its transactions in a public blockchain
- *should* store its data in a public blockchain

Internal currency

According to Raval, profit is a cornerstone of any successful, robust and sustainable application [56, p. 9]. Because traditional revenue streams (e.g. fees, advertising, subscriptions) are not applicable without preventing the possibility of a fork, he proposes an internal currency⁹ that is required to use the service [56, p. 11], hoping that it will appreciate in value by being listed on an exchange. Nevertheless, not every application is designed for profit.

- *can* use an internal currency for monetization
- *can* use an internal currency for access / service usage

On the other hand, using an internal currency to reward the contribution of value is especially important for type I **dApps** which employ their own blockchain and thus require an incentivization structure that keeps both miners and developers active [56, p. 9].

- Type I *must* use an internal currency to reward the contribution of value
- Type II *can* use an internal currency to reward the contribution of value

⁹ Type I: Blockchain-native cryptocurrency, Type II: Smart-contract issued token.

Lastly, Johnston et al. specify that tokens shall only be generated according to a predefined cryptographic algorithm. This is inherently true for type I **dApps** which issue their internal currency as a reward for completing the cryptographic challenge (e.g. proof-of-work) [51, pp. 3–4]. In this context, tokens are considered to be a feature of type II **dApps** (comp. **Decentralized consensus**). Therefore, their generation is not directly tied to cryptographic algorithms, but rather to the program’s control flow.

- Type I *must* use a cryptographic algorithm to generate its internal currency
- Type II *can* only generate its internal currency via a smart-contract

Decentralized protocols

Although often required, storing massive amounts of data in a blockchain defeats its design purpose of a simple transactional log. Moreover, this would diminish the incentive to maintain the network because the cost to participate (i.e. disk storage and bandwidth) will become considerably higher than the reward paid if many applications follow this trend. Hence, other solutions should provide methods for storing data in a decentralized way that is robust and as trust-less as possible [56, pp. 25].

- *can* use a decentralized storage solution

Similarly, message-intensive applications should not (entirely) rely on a blockchain for operation. This is due to the fact that every message will be stored forever and is public by default.

- *can* use a decentralized messaging solution

The definition presented within this section purposely does not make any assumptions about the user interface or a **dApp**’s resiliency. Command-line interfaces qualify just as much as mobile native apps, whereas resiliency can be maximized by employing additional decentralized protocols. More importantly, the primary focus and goal of any **dApp** developer should be to give users the confidence that a product works as promised by solely relying on open, decentralized peer-to-peer infrastructure services that can be inspected for functioning from end-to-end.

2.2.3. Infrastructure Model Comparison

Essentially, smart-contracts can be compared to web services that are open to the public and perhaps even open-source [62, p. 120]. Going further, it is proposed that the architectures of the corresponding applications can be compared through **Figure 2.5** in which matching

colors indicate equal functional purposes. For simplicity, all components of a centralized application are shown to run on the same server even though these will most likely be distributed as well. Also, not all applications will require all of the components displayed therein.

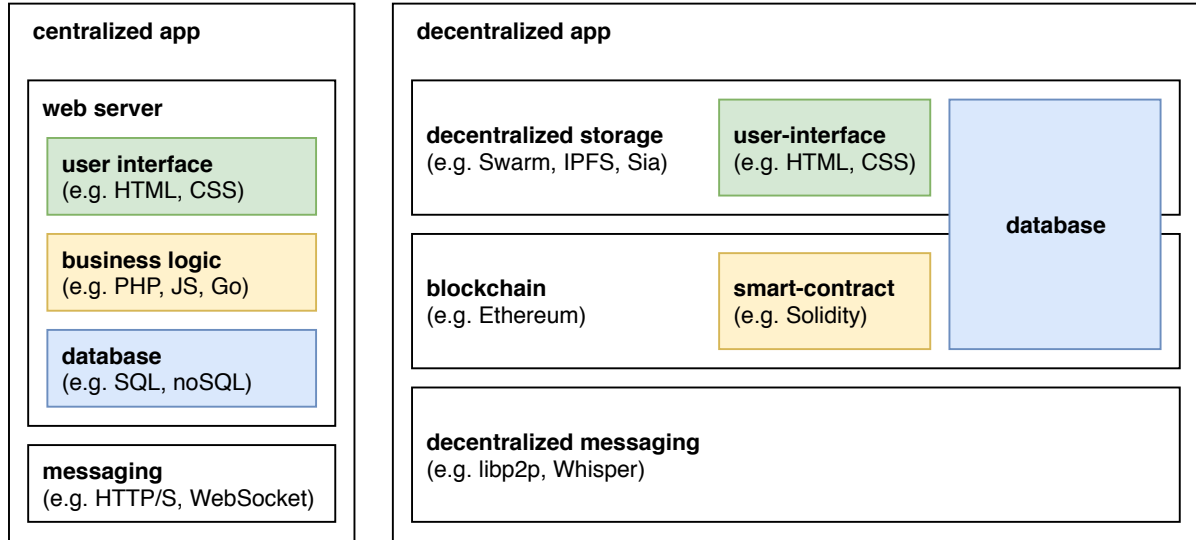

Figure 2.5.: Infrastructure model comparison of centralized and decentralized applications

Yet, a very important distinction must be made when comparing the two. Consider the following fictional example:

A trendy new non-governmental organization hopes to raise funds for charities and promises that 90% of the collected donations will be directed towards the cause. What separates this organization from others is their effort to be as transparent as possible. Therefore, the source code of this web application is submitted to an open-source platform and now awaits inspection by the community.

At this point, it should become evident that there is no practical way of verifying whether this code will really run in the background and thus, process incoming donations as promised. This is due to the centralized infrastructure model embodied by the web. Nowadays, most hosts sit behind the closed doors of a large-scale data center.

By utilizing a smart-contract platform built on top of a public blockchain, users can be almost certain that an application works as advertised. The smart-contract is part of the blockchain and may therefore be downloaded and fingerprinted (i.e. hashed) against the publicly advertised code repository. It is this exact property that has already solved the trust issue encountered by currencies and which, in the future, will eliminate those concerns raised by today's centralized applications. Of course, there is still the possibility of

fraudulent inputs, although this can be largely suppressed if the user interface is provided as a website.

2.2.4. Tokens

By introducing a digital equivalent, blockchain has evoked a semantic change for the word token originally used to mean privately-issued coin-like items that have insignificant value and are designed for a single purpose (e.g. transportation-, arcade- or laundry tokens). Now, tokens are used to simultaneously convey ownership, access rights, as well as the right to vote, for instance. Moreover, they are more easily exchangeable, a pitfall commonly cited [24, p. 173]. According to Antonopoulos and Wood, this could make tokens quite valuable when used in a way that does not re-create the conditions that made physical tokens worthless [24, p. 178], hereby hoping for industry wide solutions.

Use Cases

Antonopoulos and Wood present the following list of possible uses. However, tokens often encompass several of these features and, much like their physical equivalents, it is hard to discern between them [24, pp. 173–174].

- Currency
- Resource
- Asset
- Access
- Equity
- Voting
- Collectible
- Attestation

Further, most projects employ tokens for two reasons: *utility* and/or *equity*. Similar to access tokens, utility tokens are those where the use of the token is required to pay for a service, application or resource [24, p. 176]. Yet, this requirement increases the barriers to adoption as the risks of broader economy (e.g. exchanges, liquidity, regulators) are added to those of the underlying blockchain technology [24, pp. 177]. Tokens should only be adopted if the application cannot work without them, not because they present a fast way to raise money while being disguised as a utility token to forego public securities regulations [24, p. 178].

Fungibility

Tokens are fungible if any single unit can be substituted for another without incurring a difference in value or function. A token is not entirely fungible if its historical provenance can be tracked, as this enables black- and whitelisting. The latter is the case for most cryptocurrencies ¹⁰. Lastly, non-fungible tokens represent unique tangible or intangible items which are not interchangeable [24, p. 175].

Intrinsicality & Counterparty Risk

While some tokens represent blockchain-native digital items, many tokens are used to represent extrinsic things. By such, consensus rules do not entirely apply and human law or agreements decide whether the transfer of ownership through tokens will be recognized. It is therefore even more important to understand who possesses the associated asset and to know what formal rules apply [24, pp. 175–176]. Leveraging tokens and smart-contracts to eliminate counterparty risk will most likely play part in future market strategies.

¹⁰ Monero pursues complete anonymity and therefore faces the possibility of being banned in Japan [23].

2.3. Ethereum

2.3.1. Overview

In line with the web3's vision of a serverless internet (comp. 2.2.1), Ethereum was designed to abstract the details of a blockchain to provide a deterministic and secure programming environment for dApps in which developers are no longer required to bootstrap the underlying mechanisms [24, p. 27]. By such, it is practically regarded as an open-source, globally decentralized computing infrastructure that executes programs, known as smart-contracts, for which the current state and transitions leading to this state are stored in a blockchain alongside a cryptocurrency called Ether (code: ETH, symbol: Ξ). However, it must be emphasized that Ether is primarily intended as a utility currency¹¹ to meter and constrain resource usage during execution which stands in stark contrast with Bitcoin's sole purpose of being a digital payment network [24, p. 23] [51, p. 1].

Compared to a general purpose computer, the main differences are that [24, p. 28]:

- state changes are governed by rules of consensus
- state of the computer is distributed globally on a shared ledger

From a computer science perspective, Ethereum may therefore be described as a deterministic but practically unbounded state-machine characterized by its [24, p. 23]:

- globally accessible singleton state
- virtual machine that applies changes to that state

2.3.2. Developer Popularity & Adoption

Naturally, and as is the case with most base layer technologies, Ethereum does not represent the only smart-contract platform available¹². Nevertheless, several key figures support the claim of Ethereum dominating this space:

- 94 of the top 100 tokens were launched on Ethereum (87% of the top 800) [65] [50]
- Ethereum ranks well above competitors (#33 vs. #72 for EOS) when comparing the traffic of dedicated sites in StackExchange network [4]

¹¹ Amusingly, Vitalik Buterin, co-founder of Ethereum, would like to use Bitcoin Cash for day-to-day transactions [73].

¹² Contenders include (alphabetically listed): Cardano, Corda, EOS, Hyperledger Fabric, Lisk, NEM, NEO, Stratis and Waves.

Moreover, Wang and Vergne argue that upon the emergence of a new, technically more advanced platform, the blockchain possessing the stronger development team and open-source community is more likely to succeed [71, p. 14]. The following points illustrate how much Ethereum’s ecosystem is focused towards developers and its community:

- StackExchange encounters mainly developer focused questions and has answered 14.3K questions (vs. 850 for EOS) [68% vs. 81% of total questions] [64, p. 6] [4]
- GitHub lists 17.5K Ethereum-related projects (vs. 3.4K for EOS & 2.5K for Hyperledger) ¹³

Most importantly, Ethereum is estimated to have around 250K developers [50], a 30-fold lead to Hyperledger Fabric, the second most active community, according to a report from Gartner [34].

Similarly, the degree of decentralization should not be neglected when considering platforms based on public permissionless blockchains. To this extent, Ethereum boasts 17.6K nodes across six continents ¹⁴ [7].

2.3.3. Concepts

In order to provide developers with a general-purpose computing architecture that runs programs everywhere, yet produces a common state secured by the rules of consensus [24, p. 31], Ethereum redefines existing concepts, while also introducing several new ones.

Accounts

At its core, the state of Ethereum is composed by objects called *accounts*, each of which has its own 20-byte address and features the following properties [72, p. 17]:

- [Nonce](#)
- Current Ether balance
- Contract code (if present)
- Storage (empty by default)

¹³ A fuzzy, top-level search was conducted on [GitHub](#) on August 15th, 2018.

¹⁴ EOS does not qualify since the 21 block producers used in its delegated proof-of-stake consensus mechanism are elected from a list of pre-approved candidates [43, p. 6] [5]. A similar case can be made for NEO which is only currently in the process of decentralization [52] [6].

Further, two types of accounts are distinguished [72, p. 17]:

Externally owned accounts (EOAs)

Accounts created by or for human users of the Ethereum network. This implies the existence of a private key which controls access to the associated funds [24, p. 13]. Such an account has no code, but can send messages by creating and signing a transaction.

Contract accounts

Accounts containing code that executes whenever a message is received from another account [24, p. 13]. Consequently, they are owned and controlled by the logic of the code stored respectively [24, p. 57]. This code allows contract accounts to read and write to internal storage and send messages. The latter unlocks additional capabilities, such as transferring Ether, creating new contracts, or interacting with existing ones [72, p. 19].

Messages & Transactions

As previously indicated, a transaction is a signed data package that stores a message which originated from an EOA. It works as expected from any cryptocurrency (i.e. it results in a transfer of value if the transaction has been confirmed and a non-zero positive amount has been specified) but has been *expanded* by three *new* additional fields for contract invocation [72, p. 18]:

- recipient
- signature (identifies sender)
- amount of Ether (denoted in Wei ¹⁵)
- *data* (optional)
- *start gas* (required)
- *gas price* (required)

On the other hand, messages are virtual objects that are never serialized [72, p. 19]. This is due to the fact that all messages can be reconstructed by replaying the transaction that triggered a contract's code to run and thus, produced the message in question ¹⁶. Moreover, they only implicitly contain the sender's address and do not allow the gas price to be specified. The reason for this is explained in the following section.

¹⁵ Smallest unit of currency, from which $1 \text{ Ether} = 1 \times 10^{18} \text{ Wei}$. Following the International System of Units, Ether's denominations have both a scientific name as well as a colloquial name that pays homage to the great minds of computing and cryptography [24, p. 40].

¹⁶ Messages are generated whenever a contract uses the **CALL** opcode [72, p. 19].

Gas

Whereas Bitcoin’s scripting language is constrained to simple true/false evaluation of spending conditions, Ethereum’s language is Turing-complete, meaning that it can execute code of arbitrary and unbounded complexity [24, p. 25]. In turn, this leads to additional security and resource management problems as it cannot be predicted whether a program will terminate or run in infinite loops to effectively cause a denial-of-service attack. To combat this attacking scheme, Ethereum has introduced a metering mechanism called *gas* which accounts for every instruction performed and assigns each a predetermined cost in units of gas¹⁷ relative to the degree of computation required or burden imposed from writing to a persistent data store [24, pp. 32–33]. For simple transactions (i.e. a payment), the amount needed has been fixed at 21K units [24, p. 153].

By requiring transactions to set an upper limit (**STARTGAS**), execution will deterministically terminate as soon as the gas consumed exceeds the gas supplied [24, p. 33]. This gas allowance applies to both the transaction itself, as well as to all sub-executions triggered through the encapsulated message [72, p. 19]. Logically, the total amount to be consumed by invoking a particular method can only be estimated because contracts can evaluate different conditions leading to different execution paths. In any case, **EOAs** are only billed for the gas actually used¹⁸ [24, p. 154].

Additionally, the **GASPRICE** field allows an originator to set the exchange rate for each unit of gas (measured in Wei per gas unit). Analogous to other cryptocurrencies, the higher the gas price¹⁹, the faster the transaction is likely to be confirmed. Still, it may also be set to zero and the transaction might even get mined during periods of low demand [24, p. 153].

With these two parameters in place, the final transaction fee, collected by miners, can be calculated as [24, p. 53] [72, p. 20]:

$$\text{fee} = \text{consumed gas} \times \text{gas price} \quad (2.1)$$

In this sense, gas is the fuel of Ethereum and has been purposefully separated as such to protect the system from Ether’s volatility in value [24, p. 152]. At the same time, developers need to think of incentives for people to use the application since invocation of a smart-contract ultimately incurs monetary costs [64, p. 4].

¹⁷ The current fee schedule can be found in [74, p. 25].

¹⁸ Assert-style exceptions consume all gas available [62, p. 75].

¹⁹ Often, the suggested gas price is calculated as the median across the last several blocks [24, p. 153]. However, gas prices are predominantly determined by miners and can therefore fluctuate unexpectedly [24, p. 54].

2.3.4. Functioning

State Transition Function

Like any (distributed) state-machine, Ethereum requires a function to transition the current state (s) to the next final state (s'). This function is defined as $apply(s, tx) \rightarrow s'$, where tx represents an unprocessed (i.e. unconfirmed) transaction. Application works as following [72, p. 20]:

1. Check if transaction is well-formed, contains valid signature and nonce
2. Calculate fee = start gas \times gas price, determine sending address from signature, subtract fee and increment the sender's account nonce
3. Set gas = start gas and take off certain quantity per byte in the transaction
4. Transfer value to receiving account and run specified contract code if present
5. If transaction failed due to insufficient funds or out-of-gas exception, revert all state changes except payment of mining fees
6. Otherwise, refund remaining gas to sender and add fee to miner's balance

Code Execution

Instead of only tracking the state of currency ownership, Ethereum tracks a general-purpose, key-value data store [24, p. 28]. More complex state transitions (i.e. not a payment) can be achieved by loading the code stored for a specific contract account into memory and running it on an emulated computer called the Ethereum Virtual Machine (EVM) [24, p. 57]. EVM code is written in a low-level, stack-based bytecode language, generated by compiling one of the many high-level languages available²⁰ (e.g. LLL, Solidity, Vyper) [72, p. 22] [24, p. 29].

In general, code execution is an infinite loop that repeatedly carries out the operation at the current program counter until the end of code is reached or an **ERROR**, **STOP** or **RETURN** instruction is detected. During execution in the EVM, code may access the value, sender and data of an incoming message, in addition to basic block header data and the global account state. Furthermore, operations have access to three types of space where data can be stored [72, p. 22]:

- stack (follows LIFO-principle with push and pop methods)

²⁰ A curated list of compatible smart-contract languages can be found at [8].

- memory (theoretically, this is an infinitely expandable byte array)
- storage (persistent key-value store)

Lastly, it must be mentioned that the [EVM](#) is modeled as a completely isolated and sandboxed process which prevents access to the network and filesystem [62, p. 19]. This has the negative effect of rendering most traditional [APIs](#) useless [56, p. 46].

Block Validation

Ethereum, by definition, is a system that allows concurrency of operations but enforces a singleton state at each mined block [24, p. 151]. To ensure that this state represents a valid state, the following block validation algorithm must be carried out by each node upon downloading a foreign block [24, p. 57] [72, pp. 23]:

1. Check if previous block exists and is valid
2. Check that timestamp is greater than that of the previous block but less than 15 minutes in the future
3. Check that block number, difficulty and various other low-level Ethereum-specific parameters are valid
4. Check that proof-of-work on block is valid
5. Set $s[0]$ = state of previous block
6. Set tx = block transaction list (with n transactions). For each i in $0 \dots n - 1$, set $s[i + 1] = apply(s[i], tx[i])$. Return an error, if any iteration returns an error (comp. [State Transition Function](#)) or total gas consumed exceeds the **GASLIMIT** ²¹.
7. Set $s_{final} = s[n]$ with block reward paid to miner
8. Verify that Merkle tree root of s_{final} is equal to root provided in block header

This procedure also directly answers the question as to where contract code will be executed in terms of physical hardware – namely, on all nodes that download and validate blocks containing transactions whose data field matches one of the methods of the recipient’s contract code [72, p. 24].

²¹ Similar to Bitcoin’s block size, the **GASLIMIT** regulates the maximum number of transactions that can be included within a block [27] [74, p. 8]. Yet instead of solely measuring storage space, it limits the amount of computation that a miner must expend.

3. Concept

3.1. Incentivized Deposit-Refund System

3.1.1. Overview

An incentivized deposit-refund system, as is outlined in the following, aims to:

- (A) bolster the portion of beverages sold in reusable packaging
- (B) prevent pollution of the environment caused by throwing away bottles
- (C) support the cause of environmental agencies

From a game theory perspective, (A) and (B) could be presumably achieved by ²²:

- rewarding consumers who purchase reusable bottles
- penalizing consumers who throw away their bottles

To translate these measures into reality, it will be necessary to alter the current deposit-refund system (see 2.1.3) so that:

- non-claimed deposits are redistributed among agencies and reusable bottle consumers
- a penalty is added onto future deposits of consumers who repeatedly pollute

Practically, this will require garbage collection agencies to report how many and which specific one-way bottles have been thrown away. Otherwise, it will not be possible to calculate the amount of non-claimed deposits and identify which consumer was last responsible for the bottle. The latter infers that bottles must be uniquely identifiable. On the other hand, such a system can only be realized if retailers forward the information that a consumer has bought reusable bottles and has thereby become eligible to receive rewards. Furthermore, to establish proper ownership, they must also report which one-way bottles a consumer has purchased. Lastly, it should be prevented that anybody can report these figures, pretend to be an environmental agency or claim someone else's rewards. This core functionality, along with the existing minimum level of service, can be expressed in terms

²² The government's sole threat to introduce a deposit-refund system did not succeed in achieving (A) (comp. footnote 2 and Figure 2.1 on pp. 3–4).

of the different interactions a certain user may have with the system. This is depicted in Figure 3.1.

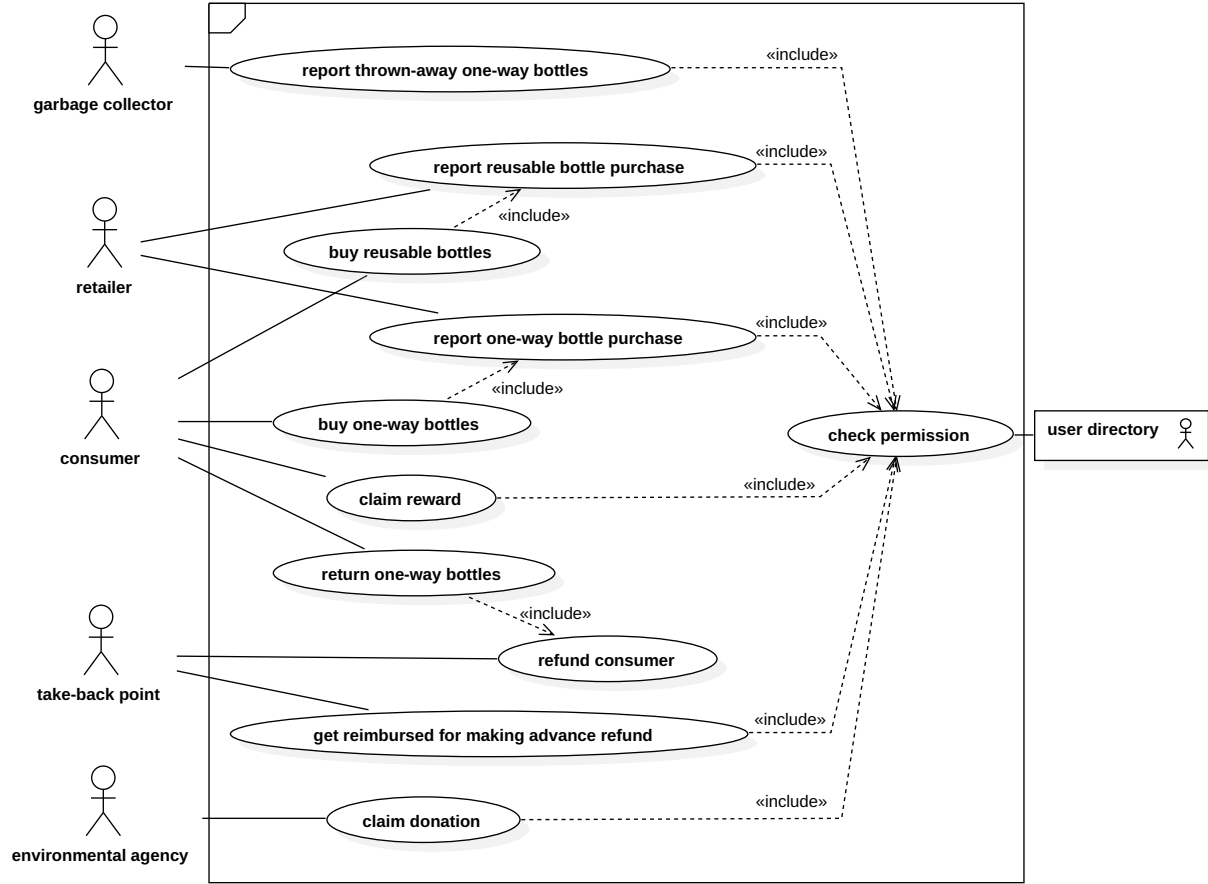

Figure 3.1.: Overview of use cases

From this overview, it becomes apparent that a revised approach will essentially incorporate an accounting layer to enable the penalization and rewarding of consumers. Basic protocols of interaction (i.e. buying and returning a bottle) should only be modified to the minimum extent needed.

3.1.2. Proposed Rules

Having given a high-level introduction to an incentivized deposit-refund system, this section aims to provide an exemplary set of rules that may constitute the underlying business logic. Again, it must be noted that this only serves as a guideline for architecting such a solution. The precise economics, psychological effectiveness and ethics introduced hereby are disregarded (comp. 1.2).

Rewards & Donations

- 50% of non-claimed deposits are reserved for donations (*agency fund*)
- 50% of non-claimed deposits are reserved for rewards (*consumer fund*)
- rewards and donations can be claimed once within a specific period
- a period's duration is set at 4 weeks
- a consumer's reward (r_c) is based on the relative amount of reusable bottles (b) he has purchased within the previous period and can thus be calculated as:

$$r_c = \frac{b}{b_{total}} \times f_c \quad (3.1)$$

where b_{total} denotes the total number of reusable bottles sold within that period and f_c resembles the consumer fund

- non-claimed rewards are withheld from the consumer by the application
- the agency fund (f_a) is evenly distributed, so that each's donation (d) will be $d = f_a/n$, where n refers to the number of approved agencies
- non-claimed donations remain available for all agencies in the next period

Penalties

- if a consumer repeatedly pollutes, he must pay a penalty on top of each deposit
- the threshold (t) to receive a penalty is set at 5 thrown-away bottles
- the penalty's value (v) is set at 0.05 €
- a consumer's penalty (p_c) is proportional to the number of bottles (b) he has thrown away during the lifetime of this system, meaning that:

$$p_c = \frac{b - (b \bmod t)}{t} \times v \quad (3.2)$$

- the penalty is refunded if the consumer returns the bottle on his own
- the penalty is seized if the bottle is thrown away or returned by someone else

3.1.3. Functional Requirements

In accordance to [subsection 3.1.1](#) and [subsection 3.1.2](#), the following functional requirements are defined as the bare minimum of features any implementation must provide in order to be used as the accounting backend of an incentivized deposit-refund system. These requirements are expressed from the perspective of an end-user who hopes to achieve different goals by using the system and are grouped by the various roles encountered (comp. [Figure 3.1](#)).

Of course, consumers and environmental agencies will also expect a method to claim the promised rewards and donations respectively, so that two additional requirements are subsequently defined.

Garbage collector

FR-01 As a garbage collector, I can report the number of thrown-away one-way bottles, so that the amount of non-claimed deposits can be calculated.

FR-02 As a garbage collector, I can report the identifier of a thrown-away one-way bottle, so that the responsible consumer can be penalized.

Retailer

FR-03 As a retailer, I can report that a consumer has purchased reusable bottles, so that he can become eligible to receive rewards.

FR-04 As a retailer, I can report how many reusable bottles a consumer has bought, so that his share of rewards can be calculated.

FR-05 As a retailer, I can report which one-way bottles a consumer has bought, so that the ownership of each bottle can be recorded.

FR-06 As a retailer, I can look up the penalty that a specific consumer must pay, so that this amount can be added onto the deposit of each bottle that he purchases.

Take-back point

FR-07 As a take-back point, I can report which one-way bottles a consumer has returned, so that the penalty, if raised, can be refunded or seized accordingly.

Consumer

FR-08 As a consumer, I can claim a reward for having purchased reusable bottles, so that I will be motivated to do so in the future, even though one-way packaging is lighter when compared to most reusable bottles.

Environmental agency

FR-09 As an environmental agency, I can claim a donation, so that my cause will be better supported through the secured funding.

3.1.4. Preconditions

While an incentivized deposit-refund system may be effective, it does assume a variety of conditions that must be put into place for it to function properly. As previously hinted, they can be described as the:

Obligation to report thrown-away one-way bottles

In addition to reporting the total number of thrown-away bottles, garbage collection must also be obliged to communicate the individual identifiers. This assumes that one-way bottles are marked with a label that is unique across all bottles in circulation. Finally, and to automate the whole process, special object recognition machinery will be required along the sorting belt of any given refuse disposal site.

Obligation to report bottle purchase

Retailers and initial distributors alike must report which particular one-way bottles a consumer has purchased. The same (i.e. quantity) goes for buying reusable bottles although this only happens through opt-in as people should not be forced to accept rewards. In both cases, it will be necessary to have consumers present a unique means of identification then they complete their purchase.

Obligation to levy penalty

Assuming that the consumer qualifies for a penalty, retailers must be impelled to impose this amount upon purchase of a bottle. This would, in turn, require an extension to cash registers so that the amount can be queried dynamically, given that the consumer has been priorly identified.

Obligation to report one-way bottle return

Similar to reporting a purchase, take-back points have to report which consumer had been responsible for returning a particular one-way bottle. Since the return

process can either be automated or executed manually (comp. [Figure 2.4](#)), different mechanisms to identify the consumer will be needed.

These prevailing conditions could be enforced by amending the system's legal basis (see [2.1.1](#)) and then integrating the relevant clauses into the contracts that [DPG](#) maintains with each participant (see [2.1.3](#)). However, the exact realization including that of the measures needed as explained above is out of the scope of this paper (comp. [1.2](#)) and thus, assumed to be satisfied for the remainder of this paper.

3.1.5. Non-Functional Requirements

Whereas functional quality stresses conformance with the design specifications, structural quality addresses non-functional requirements such as security and maintainability [[48](#), p. 2]. Together, both can be used to constitute the evaluation framework for measuring a system's quality, better known as Quality of Service ([QoS](#)). [Liu, Ngu, and Zeng](#) argue that it is not practical to come up with a standard model of attributes because [QoS](#) is a broad, context-dependent concept [[46](#), p. 67]. Therefore, the following list of desired structural properties is based on those already encompassed in the current deposit-refund system or those which are absolutely necessary to implement an incentivized version.

Access Security

NFR-01 The system shall distinguish between authorized and non-authorized users. More specifically, the individual features outlined above shall only be accessible to their designated user.

Availability

NFR-02 The system shall be available for use between the hours of 6:00 am and 24:00 pm, which is justified by the fact that most sales and returns happen within this timeframe. Clients must therefore maintain a backlog of unsent reports and transmit them at the next possible point in time.

Cost

NFR-03 The system shall be no more costly in operation than it currently is. Total membership and bottle registration fees may be taken as a baseline (see [2.1.3](#)).

Scalability

NFR-04 The system shall be able to handle all user requests and by such, shall be scalable to support unlimited growth in the number of actors, reports and claims.

Efficiency

NFR-05 The system shall execute any request by the end of the day to ensure the timely application of penalties, as well as to have a proper statement ready by the end of the month.

Integrity

NFR-06 All monetary amounts (i.e. rewards and donations) must be calculated accurately before being rounded down to two decimal places. The latter ensures that no more funds are distributed than are available. Additionally, only integer figures may be reported and must be recorded as is.

3.2. Architecture

3.2.1. Smart-Contract as a Clearing House

The biggest roadblock to implementing an incentivized deposit-refund system (see 3.1) is given by the fact that DPG has decided against using a central clearing mechanism to settle refund claims of take-back points (comp. [Administration by Deutsche Pfandsystem GmbH](#) on [page 6](#)). Instead, refund claimants must invoice the initial distributor who produced the bottle that was taken back, and must then present data proving the number of accepted bottles (comp. [Deposit-Refund Cycle](#) on [page 8](#)). This design choice is easily explained because the law mandates that: “a deposit is to be charged by the distributor and each subsequent retailer” (comp. [Legal Basis](#) in 2.1.1). Obviously, transferring the deposit to an escrow account afterwards would not lead to any noticeable benefits compared to a direct settlement. Still, such a change in course will enable an incentivized deposit-refund system to be implemented. Depicted in [Figure 3.2](#) is the transfer of a deposit to an escrow account.

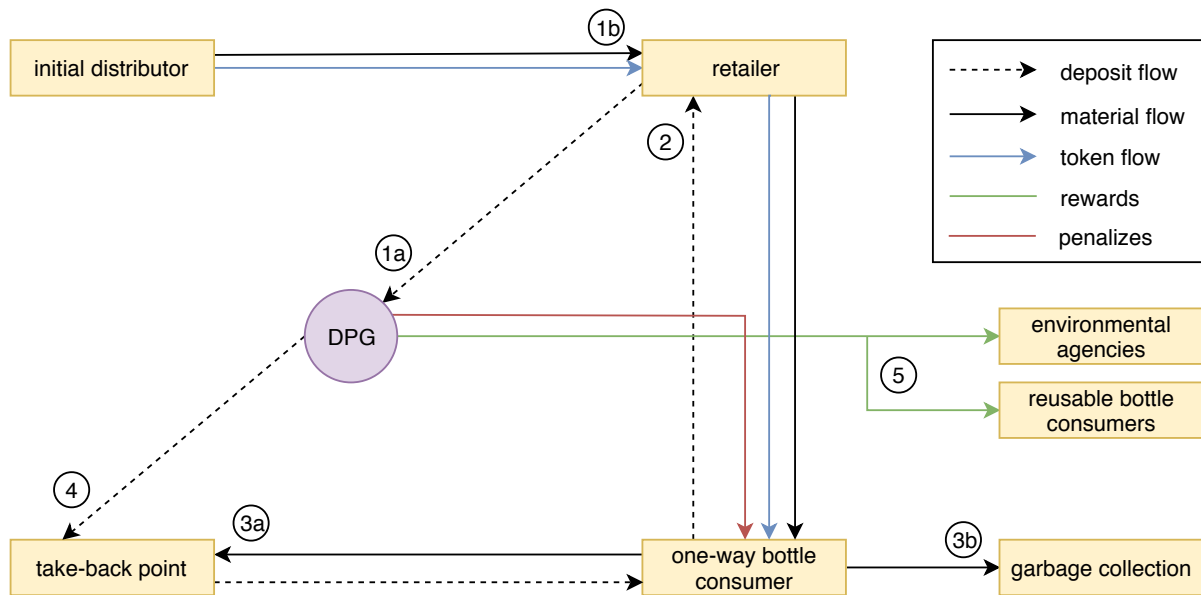

Figure 3.2.: Deposit-refund cycle in the future ²³

Leveraging Ethereum’s decentralized application platform and built-in cryptocurrency (see 2.3.1), DPG could provide participants of the deposit-refund cycle with a fully autonomous method for settling refund claims by deploying a smart-contract that would act as a central clearing house and simultaneously allow for the incentivized structure put forward. A semantic change to the regulatory underpinnings would not be required.

²³ An extended version detailing the three differently balanced accounting states (comp. 2.1.3) can be found in the [Appendix B](#) on [page 75](#).

In order for all this to work, the very first deposit charged for a one-way bottle must be converted to Ether and sent to the smart-contract (step 1a of [Figure 3.2](#)). At the same time, a non-fungible token (see [2.2.4](#)) representing the newly introduced bottle must be created using the bottle's unique identifier and associated (step 1b of [Figure 3.2](#)) with the address of the purchaser's EOA (see [2.3.3](#)). This means that the only permitted means of identification will be an Ethereum address. Keeping in mind the actor's various obligations (see [3.1.4](#)), the remainder of the system will be implemented as following:

- (2) The deposit of a one-way bottle is still directly paid to the retailer upon each subsequent sale and as already indicated, not again transmitted to the smart-contract. However, should the consumer qualify for a penalty (see [3.1.2](#)), this penalty (converted to Ether) will be sent to the smart-contract along with the purchase report itself. Furthermore, each report causes the token to be re-associated with the new consumer. In case the previous owner had to pay a penalty ²⁴, that amount will be credited to him for later withdrawal as he is not responsible for the bottle anymore.
- (3a) By returning a one-way bottle, the accompanying report triggers the smart-contract to compare the consumer's identity with that recorded for the bottle (i.e. that associated with the token). Should these match, the penalty will be credited for later withdrawal. Otherwise, the penalty is to be withheld (comp. [3.1.2](#)). Irrespective of the outcome, the token is destroyed meaning that the bottle's identifier could be reused in the future. Additionally, take-back points must physically refund the consumer (comp. [Obligation to levy deposits on beverage packaging on page 3](#))
- (3b) Should the consumer decide to throw away a one-way bottle, this information is (likely) to be reported by garbage collection sooner or later and will trigger an increase in the responsible consumer's record of thrown-away bottles, which is used to calculate his penalty (comp. [Equation 3.2](#)). Assuming that a penalty had been paid for this bottle, it is withheld (comp. [3.1.2](#)). Lastly, the token is burned and the number of bottles which have been thrown away in the current period is incremented, as is required to correctly calculate [Equation 3.1](#).
- (4) Since take-back points still directly refund consumers, settlement for these advance payments is needed. This happens by transmitting the same signed dataset which is used today and produced either by a reverse vending machine or a commissioned counting center (see [2.1.3](#)). The smart-contract can then verify the payload's signature, after which a message with equivalent value in Ether will be sent to the refund claimant's (i.e. the caller's) address.

²⁴ Even though unlikely, this indicates that a retailer has lost or thrown away one-way bottles.

- (5) Environmental agencies can simply claim their donation by signing a transaction and addressing it to this smart-contract, though, for it to work, the encapsulated message must contain the appropriate function signature (see 2.3.3). Determining that a caller is indeed an environmental agency happens by looking up his approval status. Likewise, eligible consumers (i.e. those who have been reported to have purchased reusable bottles) can claim their reward in the same fashion with the difference being that permission does not have to be checked since the reward amount is not statically calculated (comp. Equation 3.1) and by such would simply result in a zero value.

3.2.2. Component Design

Striving for a component-based design represents one of the most important best practices in software engineering because it facilitates developers in maintaining a complex system by decomposing it into parts that are easier to conceive, understand and program. At the same time, the process of dismantling a system should not happen arbitrarily but rather attempt to take the application's domain structure into account to reduce the likelihood of having to remedy large parts afterwards. Accordingly, Figure 3.3 showcases the individual components that have been identified as being essential to realizing the high-level architecture presented beforehand.

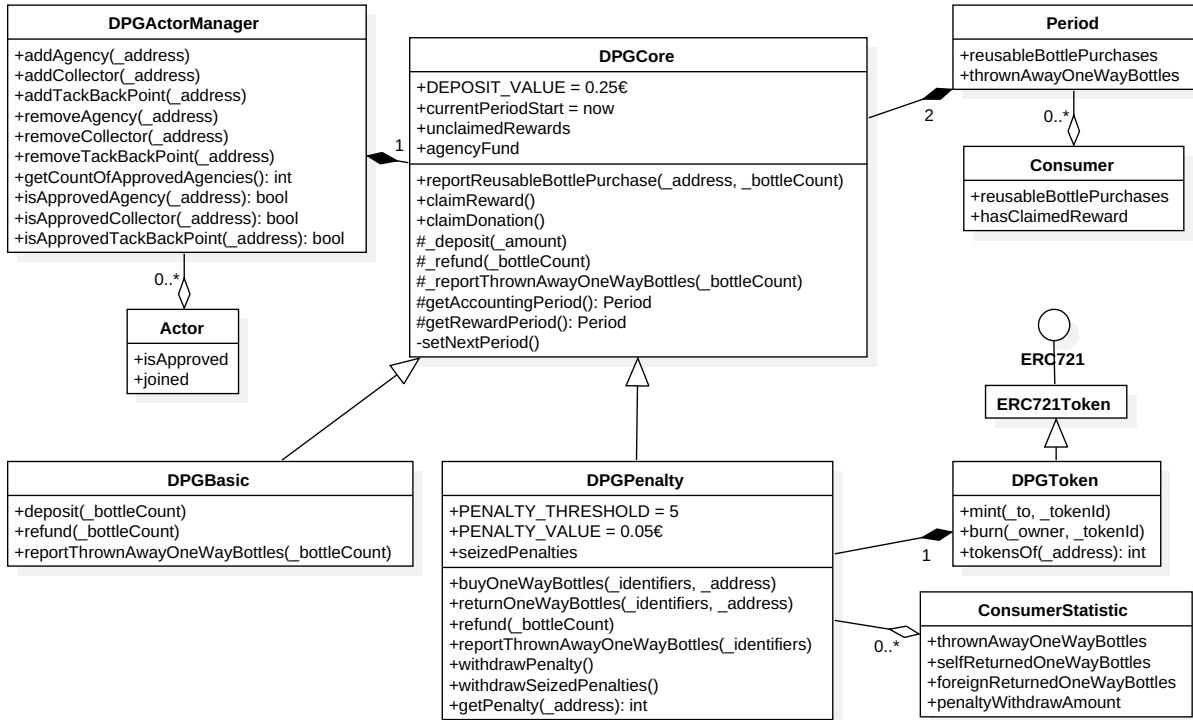

Figure 3.3.: Class design model

The classes (i.e. contracts [62, p. 75]) encountered within this (loosely typed) conceptual model can be categorized by the role they take in abstracting the system:

Accounting

As mentioned in subsection 3.1.1, some kind of an accounting layer will be needed to reward reusable bottle consumers. Here, a smart-contract called `DPGCore` will take upon this task and provide actors with `FR-01`, `FR-03` and `FR-04`. Since all reported figures are tied to a specific timeframe (i.e. the current period) and rewards can only be claimed for the past timeframe (comp. 3.1.2), `DPGCore` maintains a reference to two distinct `Periods`. Each period tracks the total number of bottles that have been thrown away in that timeframe, as well as the number of reusable bottles a particular `Consumer` has purchased. The connection to both properties allows `FR-08` and `FR-09` to be implemented within the same contract. Finally, it makes available two additional functions that for one, enable the settlement process outlined above and two, offer the ability to lock down a deposit that has been transmitted by an initial distributor (comp. 3.2.1).

By taking a closer look at the conceptual model presented, one can make out the fact that it will not be possible to directly put in a claim to be reimbursed, report a thrown-away bottle or lock up a deposit because the methods are marked as protected. Consequently, they can only be exposed through inheritance. This behavior is intended considering that the penalty can be regarded as an extension to an incentivized deposit-refund system ²⁵ and by such, requires the `APIs` to be extended with additional arguments that capture the individual bottle identifiers. Further, this design choice will break up the monolith and simplify deployment should it be decided that a penalty is not needed for production, in which case the subclass `DPGBasic` can be used out of the box.

Access Control

To relieve `DPGCore` of the duty to additionally have to track which addresses resemble approved environmental agencies, garbage collectors or take-back points, `DPGActorManager` has been established as a separate contract. It is advised that the same or some other key pair in possession of `DPG` is used to deploy this smart-contract, as only the owner (i.e. the deployer) will be able to add or remove additional `Actors`. Communication between `DPGCore` and `DPGActorManager` will happen by exchanging messages (see 2.3.3). All in all, this will ensure `NFR-01` in regard to unauthorized donation claims, thrown-away bottle reports and bottle returns. Despite these measures, another, more concerning authorization scheme is still undefined.

²⁵ As the name implies, incentivization primarily refers to rewarding reusable bottle purchases.

Prevention of unauthorized (reusable ²⁶) bottle purchases could be done using at least one of the two following items:

- signed purchase receipt (similar to refund claim)
- list of approved retailer addresses

Both options would either require a change to existing cashier systems or mandate retailers on all trade levels to register with **DPG** in order to capture their identity, as currently, this can only be done for initial distributors and take-back points (comp. 2.1.3). On the other hand, option number one would solve two additional problems. First, anybody will be able to verify the report's contents and secondly, it can be ensured that the same purchase will not be reported twice. It is therefore highly recommended that signed receipts be utilized throughout the system, in which case **DPGActorManager** would only have to maintain a list of approved environmental agencies, provided that no unauthorized party can generate such a receipt.

Penalization

Partially discussed above and in subsection 3.2.1, a penalty arises from repeatedly detecting that a consumer has thrown away one-way bottles. Detection occurs after garbage collection reports the identifier of a particular bottle, for which then the corresponding token is retrieved along with its owner. This **DPGToken** will be based on OpenZeppelin's reference implementation of the **ERC-721** non-fungible token standard and even though reuse leads to additional project dependencies, it is still very much desirable because the underlying codebase is regularly tested and community-audited ²⁷ [10].

By default, OpenZeppelin's **ERC721Token** contract does not allow users to mint new or burn existing tokens [10]. Therefore, subclassing must be used to expose these protected methods. At the same time, a barrier will be needed to prevent arbitrary usage. Generally, it can be argued that tokens shall only be managed by the application as a result of having received a report. To guarantee this behavior, all function calls within **DPGToken** will be restricted to **DPGPenalty**, hereby creating a fully autonomous debt-tracking entity, meaning that no human will be able to transfer their tokens in an attempt to get rid of the return responsibility.

One consequence of separating the penalty's logic from **DPGCore** (comp. Accounting on page 35) is the need for an additional data structure that tracks how many one-way bottles a particular consumer has thrown away. This structure is given by

²⁶ Non-existent authorization would allow attackers to bluntly increase their share in rewards.

²⁷ \$4.5 Billion worth of digital assets are powered by OpenZeppelin's smart-contracts [9].

`ConsumerStatistic`. Only now, `DPGPenalty` will be able to implement [FR-02](#), [FR-05](#), [FR-06](#) and [FR-07](#), during which some of the functionality inherited from `DPGCore` will be re-encapsulated to add the bottle identifier as a function argument. In line with [NFR-03](#), it will be possible to specify multiple bottles at once. Transaction cost (see [2.3.3](#)) reductions like these should be utilized whenever possible.

3.2.3. Conversion of Deposits

To this point, it has been assumed that each deposit will be exchanged for Ether of equal value. Considering Ethereum's volatile nature and that of almost any cryptocurrency, this procedure poses a serious concern when thinking about the reward or settlement process. In the worst case, the fluctuation could diminish all of the locked down funds, requiring `DPG` to either reject reimbursement claims or go into debt themselves. Two solutions can be thought of depending on the type of blockchain used in production:

Ethereum Main-Chain

When using Ethereum's public permissionless blockchain, fluctuations are inevitable. However, projects known as stablecoins (e.g. Tether, MakerDAO, Digix) attempt to create a cryptocurrency of constant value. Many of these are backed by a collateral, pegged to traditional fiat currencies or assets (e.g. 1 gram of gold) and most importantly, are traded as fungible (see [2.2.4](#)) Ethereum tokens [\[60\]](#). Despite each project having its own drawbacks, such a stablecoin could be utilized to better safeguard the funds by:

- acquiring adequate amount of stablecoin tokens upon receiving a deposit
- reimbursing refund claimants with stablecoin tokens

Of course, this would happen completely automatically and could be achieved through a separate proxy contract that interacts with a decentralized exchange before returning control to the actual contract method called.

Private Deployment

A more predictable approach involves permissioned blockchains, commonly referred to as private blockchains [\[75, p. 37\]](#). These are operated by an authorized set of miners who generally use Ether at constant value [\[75, p. 36\]](#). Ergo, the solution can be used as is, though it is assumed that:

- `DPG` operates a public fixed-price exchange at which internal Ether can be sold
- actors and consumers can freely transact and create accounts

The system would then be used with the following peculiarities:

- initial distributors exchange deposit for adequate amount of internal Ether
- agencies, consumers and claimants exchange their internal Ether when needed

Now, one may suggest that a similar approach could be taken in a public blockchain environment if a second token representing a constant deposit value is used. The problem, however, is that tokens cannot be passed as a function argument. This is due to the fact that tokens are merely a recoding in application state which means that a particular contract has used its storage to remember how many tokens any given address possesses [24, pp. 181, 193]. At the same time, this is also completely true for Ether itself with the exception being that miners automatically deduct one's balance should they see that a transaction has specified a non-zero positive amount of Ether (comp. [State Transition Function](#) on [page 23](#)).

3.2.4. Design Rationale

Accountless

Modeling the entire system as a series of interactions with a smart-contract is a deliberate design choice because, by definition, it prescribes all users to be authenticated with each request. This is due to the fact that only the private-key owning entity can sign transactions for that particular address (comp. 2.3.3) which allows for effortless authorization simply by maintaining a list of approved addresses. More importantly, consumers will not be required to register with yet another service just to leave their bank account details on a centralized server. A plus, considering that such a server is definitely more vulnerable to attacks than the decentralized ownership model embodied by public-key cryptography ²⁸.

Withdrawal Pattern

There are two particular reasons as to why refunded penalties will be credited for later withdrawal instead of being sent to the owner directly or paid out as part of the bottle return process. First, the withdrawal pattern generally represents an Ethereum best practice because it avoids reentrancy attacks [62, pp. 121, 169]. This is also one of the reasons why rewards and donations have to be withdrawn. Secondly, it would be very impractical to incorporate this step into the bottle return process, as reverse vending machines would

²⁸ A secure, non-constantly connected storage medium offers the greatest degree of protection against private-key theft. Devices known as hardware wallets (e.g. Ledger Nano S, Trezor) have been specifically designed for this purpose [75, p. 15].

otherwise have to first look up the penalty and convert it to fiat. Alternatively, the amount could be refunded directly, although this would require take-back points to keep an additional signed record and submit that record as part of a refund claim.

Structural Properties

From here, multiple statements will be made as to how a blockchain-based solution performs in respect to the non-functional requirements defined in [subsection 3.1.5](#). As before, the type of blockchain (i.e. public or private) has to be taken into account.

Availability (NFR-02)

Public

The application will most certainly experience 100% availability because the likelihood of all 17.6K miners (comp. [2.3.2](#)) going offline is extremely low. As such, it will not be necessary for clients to maintain a backlog of unsent reports. Furthermore, the transaction pool will act as a backlog, should Ethereum experience an overly high demand in which it is unable to directly process a request.

Private

[DPG](#) will be fully responsible for ensuring continuous uptime, although the system's distributed nature will permit multiple nodes to go offline.

Costs (NFR-03)

Public

Assuming a constant gas price and distribution of request types, the operating costs (in Ether) will always be proportional to the application's traffic (i.e. number of contract invocations) since only the actual computation expended by a miner will be billed (comp. [2.3.3](#)). The one-time fee paid for deployment is negligible.

Private

[DPG](#) will have to pay for the infrastructure. Transactions will be free of charge, provided that the yearly membership fees cover the infrastructure costs (comp. [2.1.3](#)).

Efficiency (NFR-05)

Presuming that a miner will not randomly leave out transactions and always prefer transactions with a higher gas price, any requests will be executed by the end of the day if their gas price has been set high enough.

Integrity (NFR-06)

Provided that the contract code is error-free, any reports will be recorded as is because all transactions are atomic [62, p. 75]. Further, all input arguments are strongly typed [62, p. 48], so that, if required, only integers will be accepted.

4. Implementation

4.1. Limitations

The following chapter will attempt to highlight the most important implementation details and explain which considerations have led to the solution given in [11]²⁹. This product should by no means be regarded as final since two important aspects are uncovered:

- conversion of deposits (see 3.2.3)
- signed receipts (see [Access Control](#) on page 35)

Also, it must be noted that all programming has been done in Solidity, a statically typed, high-level language that was influenced by C++, Python and JavaScript [62, p. 5]. Alternatives have not been considered because Solidity represents Ethereum’s most popular language [24, p. 21].

²⁹ The accompanying class implementation model can be found in the [Appendix C](#) on page 77.

4.2. Accounting

realized via DPGCore

In this context, accounting refers to the task of tracking how many reusable bottles a particular consumer has bought in a given timeframe, while also noting down the total number of one-way bottles that have been thrown away in that same timeframe (comp. [Accounting](#) on [page 35](#)).

4.2.1. A/B Scheme

?? states that the timeframe should be set to 4 weeks, which has literally been done by utilizing one of the six time unit suffixes available [62, p. 68]:

```
1 uint public constant PERIOD_LENGTH = 4 weeks;
```

Listing 4.1: Definition of period length

As previously explained, it will only be necessary to keep an account of the two most recent periods (comp. [Accounting](#) on [page 35](#)). By such, the application can be thought of as alternating between two data structures of which one represents the current period used for incoming reports, while the other determines a consumer's reward. Of course, this will require a reset of the older period as soon as a switch takes place. [Figure 4.1](#) aims to illustrate this behavior as time progresses.

Figure 4.1.: Accounting timeline

Internally, switching is realized by using a third variable called `currentPeriodName` that tracks which of the two data structures (i.e. A or B) should be used for new reports. For clarity, an enumeration called `PeriodName` is defined with the same possibilities. Accordingly, the opposite of the current value will then represent the past period. This technique is detailed in [Listing 4.2](#).

```

1 enum PeriodName { A, B}
2
3 PeriodName private currentPeriodName = PeriodName.A;
4 Period private periodA;
5 Period private periodB;

```

Listing 4.2: Declaration of periods and definition of current period tracker

In order to avoid repetition, two additional helper functions are implemented to provide a constant access interface. Listing 4.3 showcases how this is done in respect to the current period. Again, the inverse logic will yield the past period.

```

1 function getAccountingPeriod() internal view returns (Period storage) {
2     return currentPeriod == PeriodName.A ? periodA : periodB;
3 }

```

Listing 4.3: Helper function to retrieve current period

Here, the function’s return type is marked as **storage**, meaning that it will return a reference to the period stored in the contract’s persistent storage (see 2.3.3), not a copy of it. This greatly simplifies persistence as changes do not have to be written back manually. Alternatively, one could also directly maintain two storage pointers that reference the data structures in a logical manner. The advantage of that approach is that no helper function will be required for retrieval, though it might obscure how the application works and therefore, contradicts with a **dApp**’s goal of establishing trust (comp. 2.2.2). Still, both possibilities have been confirmed to work equally.

At this point, it should be noted that a function declared as **view** promises to not modify the contract’s state³⁰ [62, p. 82]. This commitment can be clearly seen in Listing 4.3 but is also enforced by the **EVM** itself [62, p. 83]. Practically, this allows nodes to perform synchronous read-only operations that are free of charge [12]. Unfortunately, calling such a function by means of transactions will still cost gas because the transaction must be stored in the blockchain even if it does not modify that particular contract storage [13].

4.2.2. Period Reset

Traditionally, resetting a period would be achieved by assigning it a new instance. Sadly, this method is not feasible because the **Period** data structure uses a mapping to assign each (consumer) address a **Consumer** data structure, which can be seen in Listing 4.4.

³⁰ **Pure** functions additionally disallow access of state [62, p. 82].

```

1 struct Period {
2     uint index;
3     uint reusableBottlePurchases;
4     uint thrownAwayOneWayBottles;
5     mapping(address => Consumer) consumers;
6 }

```

Listing 4.4: Period data structure

As is often the case, this limitation can be traced back to gas (see 2.3.3). Considering that mappings are virtually initialized such that every possible key exists and is mapped to a value whose byte-representation is all zeros [62, p. 62], this behavior is explained by the fact that one cannot provide enough gas to pay for the 2^{256} operations needed for a reset without exceeding the block’s GASLIMIT (see footnote 21). Therefore, `delete` has no effect on whole mappings [62, p. 63].

```

1 struct Consumer {
2     uint reusableBottlesPurchases;
3     bool hasClaimedReward;
4     uint lastResetPeriodIndex;
5 }

```

Listing 4.5: Consumer data structure

A simple workaround is given by Listing 4.5 in which an additional property called `lastResetPeriodIndex` is associated with each consumer to remember the period (index) in which the consumer’s attributes were last reset. Should this index be smaller than the contract’s `currentPeriodIndex`, a reset must occur before any attribute may be updated. Logically, the `lastResetPeriodIndex` must then be set to the `currentPeriodIndex` to prevent the consumer from being reset each time.

4.2.3. Period Advancement

Solidity function modifiers can be used to automatically check a condition prior to executing a function [62, p. 79]. This application implements a modifier called `periodDependent` to ensure that reports always attribute to the most current period and do not change the results of the past one. By such, it may be regarded as the switch in the A/B scheme outlined before.

Practically, this means that the application will check whether the current period’s duration has exceeded the `PERIOD_LENGTH` (see Listing 4.1). If so, the application switches periods

before returning control to the method called, which is symbolized by an underscore [62, p. 81]. Listing 4.6 displays this logic, where `now` is an alias for the current block timestamp³¹, `setNextPeriod()` represents the function used to actually switch periods, and `currentPeriodStart` is self-explanatory. All timestamps are given in unix epoch format [62, p. 29].

```
1 modifier periodDependent() {  
2     if (now < currentPeriodStart.add(PERIOD_LENGTH)) {  
3         _;  
4     } else {  
5         setNextPeriod();  
6         _;  
7     }  
8 }
```

Listing 4.6: Function modifier to advance period

Finally, Listing 4.7 demonstrates how this modifier is applied to functions.

```
1 function reportReusableBottlePurchase(address _address, uint  
    _bottleCount) public periodDependent
```

Listing 4.7: Function signature to report reusable bottle purchases

³¹ Timestamps can be influenced by miners and are only guaranteed to be somewhere between the timestamps of two consecutive blocks of the canonical chain [62, p. 65].

4.3. Access Control

realized via `DPGActorManager`

In its most basic form, access control can be realized by maintaining a list of authorized addresses. For an incentivized deposit-refund system, this list must at least cover all environmental agencies which should be able to claim a donation (comp. [Access Control](#) on [page 35](#)).

4.3.1. Storage Layout

Even though access control could be realized through a simple list (i.e. an array), gas consumption diminishes this approach's efficiency because the average cost of checking whether a given address is contained in the list is linear to the number of approved addresses (i.e. $O(n)$). Moreover, this cost cannot be predicted and may very well exceed the block's `GASLIMIT`, causing the contract to be stalled [62, p. 122]. Instead, a mapping is used to ensure $O(1)$ lookups.

```
1 struct Actor {  
2     bool isApproved;  
3     uint joined;  
4 }  
5  
6 mapping(address => Actor) private collectors;
```

Listing 4.8: Declaration of approved agencies and Actor data structure

4.3.2. Function Modifier

As mentioned in [subsection 3.2.2](#), only `DPG` should be able to add or remove parties. Again, this is easily realized through modifiers and even promoted as one of its first and foremost use cases [62, p. 80]. Because this functionality will be needed quite often (comp. [Figure C.1](#) on [page 77](#)), the project extracts the logic into a separate contract that can be inherited from. From [Listing 4.9](#) it can be seen that only the address passed as part of the constructor will be able to call a function that is marked as `onlyOwner`. In all other cases, the call will revert and refund the remaining gas since the `require()` statement cannot be fulfilled [62, p. 75].

```

1 contract Ownable {
2     address public owner;
3
4     modifier onlyOwner() {
5         require(msg.sender == owner);
6         _;
7     }
8
9     constructor(address _owner) public {
10         owner = _owner;
11     }
12 }

```

Listing 4.9: Ownable contract

Specifying which address should become the contract owner may happen either directly in the inheritance list or as part of the derived constructor, known as the modifier-invocation-style. This is true for all constant base constructor arguments [62, p. 89]. Both options are shown in Listing 4.10, where `msg.sender` is the sender of the message (or transaction which encapsulated the message [comp. 2.3.3]). Consequently, both lead to the same desired result in which the deployer becomes the owner.

```

1 // inheritance list
2 contract DPGActorManager is Ownable(msg.sender) { }
3
4 // modifier-invocation-style
5 contract DPGActorManager is Ownable {
6     constructor() public Ownable(msg.sender) {}
7 }

```

Listing 4.10: Inheriting from Ownable contract

4.3.3. External Interface

One result of extracting functionality into a separate contract is the need for an external interface that specifies which functions can be called by other contracts. For this purpose, Solidity provides two types of visibilities: `external` and `public`, the difference being that `external` functions cannot be called internally [62, p. 77]. What this implies will be explained in the following [62, pp. 57, 69]:

Internal Call (`f()`)

Internal function calls are translated into [EVM](#) jump instructions. The current

memory is not cleared and by such, allows references to be passed very efficiently. Only functions within the same contract can be called like this.

External Call (`this.f()`)

External function calls are executed via a message call. All function arguments have to be copied to the `calldata` location, which is a non-modifiable, non-persistent area used solely for function arguments. Callers can specify the amount of Wei and gas.

A general recommendation is to use `external` if that function is only expected to be called externally, meaning that it will not be needed by the contract itself [14]. Moreover, `external` functions are sometimes more efficient when dealing with large arrays of data [62, p. 77]. Last but not least, `external` functions have the potential to reduce upfront storage costs. Consider the following example:

```
1 import "./DPGActorManager.sol";
2
3 contract DPGCore {
4     DPGActorManager internal actorManager;
5
6     constructor(address _actorManager) public {
7         actorManager = DPGActorManager(_actorManager);
8         ...
9     }
10 }
```

Listing 4.11: Sharing external contract interface via inheritance

From Listing 4.11 it can be seen that `DPGCore` declares a variable called `actorManager` which is of type `DPGActorManager`. This variable will be defined during construction by taking the address of an already deployed `DPGActorManager` instance and casting it to this type. Behind the scenes, `DPGCore` will be forced to inherit all of the bytecode from `DPGActorManager`, resulting in a potentially large code of its own [15], even though none of the `private` or `internal` properties of `DPGActorManager` can be used.

On the other hand, interfaces will limit this inheritance to the critical Application Binary Interface (ABI), which is the standard way to interact with contracts, both from outside the blockchain and for contract-to-contract interaction [62, pp. 93, 133]. The bytecode will be much smaller and less likely to run into an out-of-gas exception when being deployed [15]. Listing 4.12 demonstrates this alternative approach.

```
1 interface IDPGActorManager {
2     function isApproved(address _address) external view returns (bool);
3     ...
4 }
5
6 contract DPGActorManager is IDPGActorManager { ... }
7
8 contract DPGCore {
9     IDPGActorManager internal actorManager;
10
11     constructor(address _actorManager) public {
12         actorManager = IDPGActorManager(_actorManager);
13         ...
14     }
15 }
```

Listing 4.12: Sharing external contract interface via interfaces

However, it must be noted that interfaces are limited to the aforementioned **external** functions and cannot define variables, structs or enums [62, p. 92]. Still, this method of sharing a contract's interface will be preferred as it supports [NFR-03](#).

4.4. Penalization

realized via `DPGPenalty` & `DPGToken`

A consumer must face a penalty if the system repeatedly detects that he has thrown away his one-way bottles. Detection occurs after garbage collection reports the identifier of a bottle. Tracking the person who is responsible for a particular bottle happens by means of associating a non-fungible token with the consumer's identity (comp. [Penalization](#) on [page 36](#)).

4.4.1. ERC-721 Token Standard

Non-fungible tokens are characterized by the fact that they cannot be substituted without incurring a difference in value, function or meaning. They represent unique tangible or intangible items (comp. [2.2.4](#)). In this case, such a token will represent a unique bottle that is indeed tangible. At the same time, this means that the very popular [ERC-20](#) standard cannot be used because it was designed for fungibility [\[16\]](#).

Before an alternative standard is presented, it should be mentioned that all token standards are a minimum specification for an implementation. They do not prescribe an exact implementation and do not prevent developers from adding functionality on top. Token standards encourage interoperability by agreeing on a set of functional requirements [\[24, pp. 198–199\]](#).

[ERC-721](#) is a proposal to standardize non-fungible tokens, also known as deeds. It places no limitation or expectation on the nature of the thing whose ownership should be tracked, requiring only that it can be uniquely identified [\[24, p. 197\]](#). Internally, this identifier will be a 256-bit unsigned integer which provides more than enough space for growth. The complete contract interface specification is given in [\[17\]](#). Here, only the most important methods shall be highlighted for subsequent discussion:

```
1 interface ERC721 {  
2     function balanceOf(address _owner) external view returns (uint256);  
3     function ownerOf(uint256 _tokenId) external view returns (address);  
4     function safeTransferFrom(address _from, address _to, uint256  
        _tokenId) external payable;  
5     ...  
6 }
```

Listing 4.13: ERC-721 contract interface specification

Compared to [ERC-20](#), two major differences can be found. First, a new `safeTransferFrom()` method is introduced. This method checks if the receiving party is a smart-contract and if so, will call `onERC721Received()`, expecting the contract to confirm the transfer by echoing the function signature. Secondly, metadata such as the name and symbol is absent. This metadata, together with a new method that should return an asset's [URI](#), has been moved into a separate optional interface called `ERC721Metadata`. For enumeration purposes, another optional interface has been defined as `ERC721Enumerable`.

4.4.2. OpenZeppelin Framework

Basic standards like [ERC-20](#) and [ERC-721](#) have emerged from experience with hundreds of applications and fit 99% of the use-cases. Choosing a standard like this will not only gain the benefits of the systems designed to work with it, but will also allow developers to reuse and extend battle-tested reference implementations [[24](#), pp. 199–200].

OpenZeppelin provides [dApp](#) developers with a library of smart-contracts that have been tested and community-reviewed [[9](#)]. This project utilizes two of its components:

SafeMath.sol

Performs math operations with safety checks that revert on error

ERC721Token.sol

Implements all the required and some optional functionality of the [ERC721](#) standard

4.4.3. Token Transfer Restriction

Having settled on a token standard and reference implementation, this section details the adjustments that have been made to guarantee the application's promise of establishing a fully autonomous debt-tracking entity (comp. [Penalization](#) on [page 36](#)).

By default, [ERC-721](#) only permits the owner of a token to initiate a transfer. Owners can also authorize an address to transfer a specific token on their behalf or even appoint an operator who is free to decide what will happen with all of the owner's tokens [[17](#)]. OpenZeppelin's implementation abstracts these authorization rules with a single method named `isApprovedOrOwner(address, uint256)`, where `uint256` refers to the token and `address` represents the caller who wishes to transfer it [[10](#)].

In this application context, none of the options should be accessible since they would allow refusal of ownership. To prevent this from happening, two changes have been introduced:

- inherit from `Ownable` contract and mark all state-modifying methods as `onlyOwner`
- return `true` in `isApprovedOrOwner(address, uint256)`

This approach infers that Solidity supports multiple inheritance since `DPGToken` must now inherit from both `ERC721Token` and `Ownable`. Listing 4.14 demonstrates how multiple inheritance is declared. Internally, this is implemented by copying code which means that only a single contract will be created on the blockchain [62, p. 88].

```
1 contract DPGToken is ERC721Token, Ownable {  
2     constructor() public ERC721Token("DPG Token", "DPG") Ownable(msg.  
3         sender) {}  
4     ...  
5 }
```

Listing 4.14: Multiple inheritance by `DPGToken`

Finally, it will be necessary that `DPGPenalty` deploys the `DPGToken` contract on its own. Otherwise, it will not be set as the owner (comp. 4.3.2). Creating a new contract on the blockchain is done via the `new` keyword and requires the full code to be known in advance [62, p. 71]. Optimizations such as those in subsection 4.3.3 are not possible.

```
1 contract DGPenalty is DPGCore {  
2     DPGToken public token = new DPGToken();  
3     ...  
4 }
```

Listing 4.15: Creating a contract from a contract

5. Testing

5.1. Test-Driven Development

Test-driven development hopes to help programmers clarify what a code segment is actually supposed to do by requiring the accompanying tests to be written beforehand. Moreover, code is developed incrementally, meaning that the next identified functionality is not implemented until the previous code passes all of its tests. Combined with an automated testing environment, this leads to the following benefits:

- Tests showcase which segments have actually been executed (*coverage*)
- Tests can be rerun to ensure that changes have not introduced new bugs (*regression*)
- Tests pinpoint the root causes of problems (*debugging*)
- Tests describe what the code should do (*documentation*)

Given the scale of the project, it has been decided to mainly rely on requirements-based testing, which is a semantic approach to test-case design where a set of tests is derived for each requirement. In a second step, scenario testing has been employed to develop test cases that cover realistic scenarios of use to which most people should be able to relate. By such, the testing methodology can be categorized as black-box testing. As always, testing can only show the presence of errors, not their absence.

Suite Name	Components	# of Tests	Requirements
Deposit Refund	Core, Actor	7	-
Report Garbage	Core, Actor	12	FR-01, FR-02
Report Purchase	Core, Actor	19	FR-03, FR-04
Penalty	Penalty, Token, Actor	29	FR-05, FR-06, FR-07
Claim Reward	Core, Actor	7	FR-08
Claim Donation	Core, Actor	11	FR-09

Table 5.1.: Test suites

In total, 85 test cases have been devised, all of which are available at [11]. Table 5.1 breaks down this number into the individual test suites and functional requirements.

5.2. Truffle Suite

The Truffle Suite plays an important role in the test-driven development process which will be demonstrated in the following section. First, two of its tools must be introduced:

Truffle

Truffle is a development environment, testing framework and asset pipeline for blockchains using the [EVM](#) [18, Truffle Overview].

Ganache

Formerly known as TestRPC, Ganache simulates an Ethereum blockchain that, by default, mines transactions as soon as they are received [18, Ganache Quickstart].

5.2.1. Network Management & Deployment

In addition to basic compilation and linking, Truffle provides developers with a one-step process for deploying multiple smart-contracts to both public and private Ethereum networks [18, Truffle Overview]. These networks can be specified within a `truffle.js` file [18, Configuration], as is given below.

```
1 module.exports = {  
2   networks: {  
3     development: {  
4       host: "127.0.0.1",  
5       port: 8545,  
6       network_id: "*" // match any network ID  
7     }  
8   },  
9 };
```

Listing 5.1: Truffle network management

Since deploying to the public Ethereum main-chain involves real fees (comp. 2.3.3), Ganache has been used throughout development. At first sight, one may believe that the `host` specified in Listing 5.1 symbolizes this intention because it specifies a localhost IP address. However, the `host` only tells Truffle where an Ethereum client resides [18, Configuration], not what kind of type it is. Furthermore, Ganache and most other Ethereum clients (e.g. `geth` and `parity`) default to the same `port` to expose their RPC services. The consequence is, that developers must either stop those clients or set Ganache to a different port in order to prevent accidental deployment [18, Deploying To The Live Network].

Before deployment can finally become possible, it is necessary to create a migration script that is responsible for staging the deployment tasks [18, Running Migrations]. Listing 5.2 displays the script used in this project.

```

1 var DPGActorManager = artifacts.require("./DPGActorManager.sol");
2 var DPGPenalty = artifacts.require("./DPGPenalty.sol");
3
4 module.exports = async function(deployer, network, accounts) {
5   await deployer.deploy(DPGActorManager);
6   await deployer.deploy(DPGPenalty, DPGActorManager.address);
7 };

```

Listing 5.2: Truffle migration script

As previously explained, the address of an already deployed `DPGActorManager` instance has to be passed to `DPGCore` as part of its constructor (comp. Listing 4.11). By virtue of subclassing, this requirement translates to `DPGPenalty` (comp. Figure 3.3). Therefore, the script `awaits` the deployer to finish that task before actually deploying the main contract. Remember, `DPGPenalty` autonomously deploys the `DPGToken` contract (comp. 4.15). Hence, it is not part of this migration.

From here, one must simply start Ganache, optionally specify its port (`-p`) and use Truffle to deploy all contracts with a single command. This process is shown in Listing 5.3.

```

1 ganache-cli -p 7545
2 truffle migrate

```

Listing 5.3: Deploying to Ganache

5.2.2. Automated Contract Testing

Having an automated testing environment is essential for test-driven development. At the same time, this stipulates that tests are written as an automated test, meaning that they will report whether they have passed or not. Other desirable attributes are given by the F.I.R.S.T. rule [47, p. 132]:

Fast

Tests should be executed quickly, so that they can be run more often.

Independent

Tests should be independent of each other, so that they can be run in any order.

Repeatable

Tests should be repeatable in every environment regardless of network status.

Self-Validating

Tests should either pass or fail, so that they do not require external judgement.

Timely

Tests should be written early, so that development is simplified.

Truffle comes standard with an automated testing framework that allows developers to write simple and manageable tests in either JavaScript or Solidity. It provides a clean-room environment while doing so to ensure that state will not be shared across test suites. Further, all tests running on Ganache will be able to utilize snapshotting, which results in an up to 90% speed improvement compared to redeploying contracts. Still, it is recommended to also run tests against an official Ethereum client as the application's release comes closer [18, Testing Your Contracts].

Right in line with the requirements and scenario-based testing outlined in [section 5.1](#), this project has settled on JavaScript tests because they are meant for exercising contracts from the outside world [18, Testing Your Contracts]. At its core, JavaScript tests are based on the popular Mocha testing framework [18, Writing Tests in JavaScript].

Example

To demonstrate Truffle's capabilities in practice, the following scenario shall be tested:

It should fail to send the reward to consumer A (even though consumer A purchased 3 reusable bottles in the past period) because the reward amount is not greater than 0 as no report of thrown-away bottles was received in the past period.

This test will be part of the DPG Claim Reward Test suite (see [Table 5.1](#)). Suites are identified by the `contract()` function, which is a special abstraction of Mocha's `describe()` environment needed to provide aforementioned clean-room features. In order to send transactions from multiple EOAs, the `contract()` function gets passed the `accounts` of the underlying Ethereum client [18, Writing Tests in JavaScript].

First off, a test suite must import all of its required components. This is done by using the `artifacts.require()` method which requests Truffle to generate a JavaScript interface for the specified Solidity contract [18, Writing Tests in JavaScript]. Both import and setup of a suite are demonstrated in [Listing 5.4](#).

```
1 const DPGBasic = artifacts.require("DPGBasic");
2 const DPGActorManager = artifacts.require("DPGActorManager");
3
4 contract("DPG Claim Reward Test", async (accounts) => {
5   let mainContract;
6   let actorManagerContract;
7
8   // hooks
9   beforeEach("redeploy contract, setup deposits ...", async() => {
10     actorManagerContract = await DPGActorManager.new();
11     mainContract = await DPGBasic.new(actorManagerContract.address);
12
13     await mainContract.deposit(10, {from: retail, value: 10});
14     await actorManagerContract.addCollector(collectorA, {from: owner});
15   });
16
17   ...
18 }
```

Listing 5.4: Setup of test suite

Notably, [Listing 5.4](#) also defines a so-called `beforeEach()` hook. As the name implies, this method will be executed before each test. By extracting common setup steps, the test becomes independent as it no longer relies on the setup that a previous test would have otherwise performed. Here, setup involves redeployment of both contracts, putting in a deposit for 10 bottles and adding `collectorA` as an approved garbage collector. Also, it shows that the last argument of each contract method may be provided as a JSON so that developers can specify `from` which of the `accounts` the transaction should be sent and what `value` in Wei will be transferred [18, Interacting With Your Contracts].

Now, the actual test may be designed. Its logic is relatively simple and self-explanatory when taking a look at [Listing 5.5](#). One particular detail should be noted. A custom `timeTravel` method has been implemented (outside of this suite) to bidirectionally travel in time by sending an `evm_increaseTime` message to the Ethereum client. To force the changes into effect, a known bug then requires a consequent `evm_mine` message [55].

```
1 it("should ...", async() => {
2     await mainContract.reportReusables(consumerA, 5, {from: retail});
3
4     await timeTravel(86400 * 28);
5     await mineBlock();
6
7     try {
8         await mainContract.claimReward({from: consumerA});
9     } catch (error) {
10         return true;
11     }
12
13     throw new Error("Did send the reward even though ...");
14 });
```

Listing 5.5: Example test case

Obviously, this test is self-validating because it will either fail with an error or succeed by returning true. Assuming that Ganache has already been started, the complete test suite can be run by entering `truffle test` [18, Testing Your Contracts].

5.3. Continuous Testing

Continuous testing describes the process of executing automated tests as part of the software delivery pipeline [25]. It should be considered a prerequisite for continuous delivery and integration [33].

Despite the limited nature of this project, a small pipeline has been set up with the help of [53] to showcase the maturity of Ethereum’s developer ecosystem and demonstrate that enterprise-grade workflows can be realized. Leveraging GitHub’s tight integration with TravisCI, a free continuous integration tool for public repositories [19], the following actions were triggered upon each commit:

- smart-contract compilation
- test suite execution
- code coverage report (available at [20])

This workflow has protected against unwanted regression when developing new features or refactoring code. Moreover, it has given the number of passing tests greater meaningfulness since those may have only covered 10% of the total codebase.

6. Conclusion and Discussion

This research has examined whether Ethereum’s decentralized blockchain-based application platform is suitable for realizing the incentivized deposit-refund system presented as part of this thesis. From a pure functional perspective, this is definitely the case although implementation generally requires a more rudimentary approach because the infrastructure imposes several uncommon but understandable constraints. None of these constraints affect the application’s functionality in any meaningful way. Still, these constraints have been highlighted throughout the application’s development process to convey the shift in thought that **HPE** must embrace in order to become a **dApp** developer.

On the other hand, acceptance of the system is highly dependent on the structural quality exhibited. Literature has shown that the type of blockchain chosen for production (i.e. public or private) influences the quality of certain structural properties. Vice-versa, two of these properties will ultimately decide the choice:

Scalability

Each hour, 1.8M one-way bottles are used in Germany. This amounts to 16 billion bottles per year [39]. Ethereum’s main-chain has processed a maximum of 1.3M transactions in a day (i.e. 15 TPS) [21]. It is safe to assume that this number will not suffice if every action of the deposit-refund cycle should be communicated immediately instead of being aggregated into a bulk report. But because this application mainly operates on a set of users that are known in advance ³², a permissioned blockchain can also be employed. In these environments, scalability is bounded by the hardware used ³³.

Cost

In this application context, a private environment does not charge for transactions since the infrastructure costs are presumed to be covered by the membership fees. The cost of invoking a particular contract method becomes more interesting if the Ethereum main-chain is indeed chosen for production. It is then given as the product of the consumed gas and gas price, the latter of which is predominantly determined by miners. Moreover, the Ether used to pay for the gas is subject to exchange rate fluctuations. By such, it does not make sense to state theses costs in dollars. Instead, [Table 6.1](#) summarizes the gas consumption that has been established as an estimate.

³² Consumers do not actively participate other than by claiming their rewards.

³³ The network can be orchestrated to scale vertically. By such, no tradeoff between decentralization and throughput has to be made when altering the blockchain parameters.

	DPGBasic	DPGPenalty
deployment	2,188,725	5,150,076
lock up deposit (buy one-way bottles)	22,206	113,166-154,196
put in claim for reimbursement	29,389	29,389
report thrown-away one-way bottles	35,894	75,024
report reusable bottle purchase	35,343	35,343
report one-way bottle return	-	66,099-66,204

Table 6.1.: Contract invocation and deployment costs (in gas) ³⁴

Factually, it can be summed that Ethereum’s ecosystem provides developers with a robust set of features and tools to implement [dApps](#) even though the knowledge base may not always be up-to-date. Unfortunately, the public infrastructure is currently unable to handle many of the traditional application loads. Also, one of the big challenges facing developers is the inherent contradiction between deploying code to an immutable ledger and a development platform that is still rapidly evolving. Smart-contracts cannot be simply upgraded.

However, this assessment only depicts the current situation. Innovation should not stop because of the limited speed and problems being experienced at the moment. Various scaling solutions are on the horizon [49]. In this sense, the state of decentralized (application) platforms should be compared to that of the early internet. Waiting for improvements will bring multiple benefits such as not having to bootstrap the underlying mining infrastructure. Furthermore, the health, resilience and censorship resistance of a network depends on having many independently operated and geographically dispersed nodes.

Finally, it must be reiterated that the implementation omits two aspects which are essential for production: signed receipts and conversion of deposits. Future research could address these topics. Other limitations result from the incentivized deposit-refund system presented herein. How likely is the adoption of such a system? Is it ethically acceptable to persuade users to return their bottles, thereby reducing the profits of one-way bottle collectors? And what happens if someone removes the bottle’s label before throwing it away?

³⁴ A full discussion surrounding the measurement of these figures can be found in the [Appendix D](#) on [page 78](#). To give an example of these costs in dollars, one may take the median gas price of 5 Gwei (valid for last 1,500 blocks) and the current exchange rate of \$290 per Ether. This leads to deployment costs of \$3.13-\$7.36 and invocation costs of \$0.03-\$0.22.

7. Summary

Imagine traveling to the Moon, not once, but 16 times in a row. This is the distance all one-way bottles sold in Germany in 2015 would cover if they were stacked on top of each other. They have produced 500K metric tons of waste, equal to the weight of 140K elephants [66]. Unfortunately, Germany’s system of returnable one-way bottles on which a deposit is paid has not positively influenced this number. More worrisome, since its introduction in 2003, the portion of reusable beverage packaging has declined by almost 36%, between then and 2015. At the same time, the system has benefitted bottlers as they are allowed to retain all non-claimed deposits.

This thesis presents the concept of an incentivized deposit-refund system, in which consumers are rewarded for choosing reusable beverage packaging but also penalized for throwing away one-way bottles. Hereby, the portion of reusable bottles could be raised and pollution of the environment prevented. However, such a system assumes a variety of conditions that must be fulfilled in order for it to function properly: each bottle is unique, each consumer is identified upon purchase, each one-way and reusable bottle purchase is reported and the identifier of each thrown-away bottle communicated.

Since any realization of such a system has to manage account balances, track the ownership of bottles and deal with deposits of low extrinsic value, the thesis goes on to propose a blockchain-based implementation. One advantage of this approach is that users are not required to register with yet another service that stores their bank account details on a vulnerable, centralized server. Centralized infrastructure increases the chances for downtime, censorship and counterparty risk, whereas open decentralized peer-to-peer infrastructure can give users the confidence that a product works as promised.

Technically, this endeavor is hindered by the fact that Deutsche Pfandsystem GmbH (DPG), the organization responsible for providing the contractual and administrative basis needed to enable a nationwide deposit-refund system, has not established a central clearing mechanism. Clearing refers to the process of reimbursing take-back points for refunding consumers, irrespective of where they purchased the bottles. To upkeep this important functionality, the thesis lays out an architecture in which the deposit charged for a bottle is converted into a cryptocurrency and sent to a smart-contract, which is a program that runs on a blockchain-based application platform. In this case, Ethereum has been utilized to offer a fully autonomous method for settling refund claims. More importantly, the system can then pay out rewards since it knows how many reusable bottles a consumer has bought

and how many one-way bottles have been thrown away. Next, to effectuate the penalty, a so-called non-fungible token is used. These tokens represent unique tangible or intangible items. By creating such a token upon purchase of a bottle and connecting it with the consumer's identity, the ownership of a bottle can be digitally tracked. Consequently, the person who would have been responsible for returning the bottle can be identified and penalized.

Throughout implementation of this architecture, Ethereum's special features and weak points are highlighted to convey the shift in thought that programmers must embrace in order to become a Decentralized Application (dApp) developer. Following implementation, the thesis outlines the test-driven development approach taken and demonstrates that enterprise-grade workflows can be achieved.

Finally, the thesis concludes that while Ethereum certainly offers the means to implement an application such as this one, its operation would be constrained if deployed today on the public main-chain. Additionally, it acknowledges that an essential component, the securing of deposits in spite of Ethereum's volatile nature, has not been put into place. Further, the concept of an incentivized deposit-refund system should be thoroughly worked out so that our future trails to the Moon can be freed of litter more quickly.

Glossary

beverage packaging

Predominantly closed packaging for foods of liquid nature intended for consumption as a drink, excluding yogurt and kefir [68, § 3].

counterparty risk

Risk that the other party in a transaction will fail to meet his or her obligations [24, p. 175].

ecologically advantageous packaging

Packaging that does not show any significant ecological disadvantages when compared to reusable packaging [41, pp. 83].

nonce

Generally, a value that can only be used once. Here: number of confirmed transactions that have originated from an account [24, pp. 17, 148].

reusable packaging

Packaging intended to be reused for the same purpose after having been used. Can be taken back, cleaned and refilled by companies who have issued such packaging. The sole intention or claim to be reused is not valid [68, § 3].

D. Conclusion & Discussion

To give an estimate on the system’s operating cost, it will be necessary to determine the amount of gas that is going to be consumed by invoking a particular contract method (comp. 2.3.3). Considering that this amount depends on the exact execution path taken, the following figures should only be referred to as an approximation.

Before a contract is deployed, developers will typically activate the compiler’s optimization program. This program operates under a trade-off situation. It can either optimize the code for initial contract deployment, meaning that the bytecode should shrink in size and thus, reduce deployment costs. Alternatively, the number of contract invocations can be taken into account in order to lower runtime costs. Because of that, the optimizer allows for a linear factor to balance between these two criteria which can be specified via the `--runs` flag [62, p. 125] [22]. Table D.1 demonstrates how this factor influences the gas consumption encountered during deployment. Also, it suggests that optimization possibilities converge beyond 10,000 runs.

optimizer	DPGActorManager	DPGBasic	DPGPenalty
turned off	776,085	2,241,200	6,595,615
1 runs	406,863	1,513,218	4,019,966
200 runs	411,842	1,549,970	4,110,315
1,000 runs	502,558	1,630,162	4,161,714
10,000 runs	518,586	1,670,139	4,631,490
100,000 runs	518,586	1,670,075	4,680,173

Table D.1.: Gas used during deployment

optimizer	add	remove
turned off	69,017	19,043
1 runs	69,356	19,383
200 runs	69,293	19,319
1,000 runs	69,018	19,045
10,000 runs	69,014	19,041
100,000 runs	69,014	19,041

Table D.2.: Average gas used by **DPGActorManager** to add and remove a garbage collector (measured across 1,000 calls)

optimizer	deposit	refund
turned off	22,301	29,486
1 runs	22,269	29,452
200 runs	22,206	29,389
1,000 runs	22,206	29,389
10,000 runs	22,206	29,389
100,000 runs	22,206	29,389

Table D.3.: Average gas used by **DPGCore** to lock up deposits and reimburse advance refunds (measured across 1,000 calls with a linear increase in payload)

optimizer	thrown-aways	reusables
turned off	36,340	35,614
1 runs	36,298	35,613
200 runs	36,101	35,550
1,000 runs	35,894	35,343
10,000 runs	35,894	35,343
100,000 runs	35,894	35,343

Table D.4.: Average gas used by **DPGCore** to report thrown-away one-way bottles and reusable bottle purchase (measured across 1,000 calls with a linear increase in payload)

The aforementioned optimization limit is seen throughout ??????, which is why further analysis will settle on `--runs=10000`. Optimizing for initial contract deployment does not make sense given the volume in requests that must be expected from a nationwide deposit-refund system. To be specific, the break-even point between 1 and 10,000 runs is reached after 280 reports of thrown-away one-way bottles ³⁵.

Thus far, all approximations can be regarded as being very close since the behavior of those components does not rely on the input arguments. These arguments are solely checked for validity. In contrary, buying a one-way bottle via `DPGPenalty` can have the effect of generating a new token or transferring ownership of an existing one (comp. 3.2.1). Both actions require a different amount of gas as is shown in Table D.6. Similarly, reporting a thrown-away one-way bottle involves looking up its owner, whereas `DPGBasic` would simply increase the number of bottles that have been thrown away.

bottles	buy	transfer	self-return	foreign-return
1	154,196	113,166	66,204	66,099
10	1,317,912	908,763	554,524	553,474
50	6,489,924	4,444,711	2,724,810	2,719,545

Table D.5.: Average gas used by `DPGPenalty` to buy, transfer and return one-way bottles (measured across 200 calls) [`solc runs=10000`]

bottles	gas used
1	75,024
10	560,020
50	2,726,797

Table D.6.: Average gas used by `DPGPenalty` to report thrown-away one-way bottles (measured across 200 calls) [`solc runs=10000`]

The `DPG Gas Cost Test` suite used to aggregate these results is available at [11].

³⁵ $\Delta D \leq 280 \times \Delta R$, where ΔD represents the savings in deployment costs achieved by setting `--runs=1` and ΔF , the increased price difference that must be paid when compared to `--runs=10000`.
